Andric and gynec characters strongly and subtly woven into the fabric of each one's personality are not unappreciated by laymen. Posture, gesture, voice and the flavoring of individual identities have long been observed and used as a means of classifying people in masculine or feminine categories. Moreover, from groups and audiences composed either of men or of women, the unerring impact of this bisexual otherness can easily be felt. But the awareness of it is more sharply focused in the impression made by a single person. One is quick to recognize the presence in a member of one sex of qualities properly allocated to the other.

To illustrate the divergence of andric and gynec impacts that radiate from groups, an excellent opportunity is afforded by a visit to a large medical clinic. Anyone who has worked long in hospitals has, no doubt, noticed the subtly different atmosphere that one senses in the men's and women's wards. There is an air of tranquillity in the latter. Neatness, decorum and patience fill the place. In some strange manner, women seem more at home there, more appropriate to bed in daytime than men. As one enters the quiet ward, one notices that all the patients seem to be reclining easily in their beds—they are mostly supine, with arms and hands crossed on the midriff or stretched resignedly beside the body. All are relaxed among their pillows. When they turn their eyes and heads to view one's approach, the expressions are not overcurious, and the motions of those who do move are unhurried and deliberate. Then, as one scans the group of patients, one's attention is sharply arrested by the woman in the third bed to the left. She is a vigorous-looking person of about fifty. A shock of white hair, cut short behind and at the sides, surmounts the powerfully modeled forehead and heavy dark eyebrows. Almost imperiously, the restless eyes observe what is going on, and the vigorous mouth and lower jaw are energetically engaged alternately in chewing gum, making thorny remarks and offering innumerable suggestions. The entire personality exudes a force that cuts sharply across the ward's passive atmosphere. The andric qualities of this person, expressed in the masculine modeling of the head, the vigorous gestures and the projection of total organismal energy, are easy to observe.

And when one enters the male ward, greater activity is at once apparent. Things are not so neat and particular as in the women's ward. Some patients are lying with knees up, others are on their sides supporting themselves by one elbow,

still others, with hands clasped behind their heads and elbows wide, are uncomfortably propped by their pillows. Occasionally, one man calls across to a friend in another bed, a radio is switched on, a patient turns awkwardly to see what an intern is doing to his neighbor. Costly of outgoing energy are all these attitudes, which accomplish little. Possibly, they express the need for satisfaction in motion, a response to the man's biologic urge to project his life force on the universe in an effort to arrive at some self-appointed goal.

Sitting at the ward's center table are three patients. Two are playing pinochle and slapping the cards down with gusto. The third attracts attention by the contrast of his attitude and appearance. This patient is an average-sized man, with large hands out of proportion to the limited thickness of his frame, and with a large pale face marked by small features. He sits quietly, hands clasped in his lap and watches the game with a tolerant and gentle smile. Often, he wags his head in mild rebuke, as though to say, "Now, children, not too roughly." When one asks him his occupation, he replies in a high-pitched husky voice with neat diction, "I'm a blacksmith, Sir." A more careful inspection reveals a paradox between this man's trade and total personality. Instead of knotty muscle, his arms and back display a smooth panniculus. Rounded shoulders, slightly prominent belly and mons veneris above curving hips and thighs bespeak a strongly feminine morphology. He patiently waits for his discharge, watches but never joins the ward activities, and creates no trouble for anyone.

From the foregoing description of differences between the impact of the andric or gynec thing that emerges from massed men or massed women, it is possible to recognize that energy, common to both groups, is utilized in quite different ways. It is not the varying magnitude of energy capacity that is the significant difference between the two phases of the androgyny. In many cases, women may be actually stronger than men. But the feminine pattern of energy utilization is fundamentally different from that of the man. The former tends to conserve and build up energy stores and to spend it cautiously. The latter, on the other hand, is prodigal of his virile forces.

The concept of the andric and gynec differences in energy utilization is not new to biologists. Thus Doncaster<sup>3</sup> reflects it in the statement that the egg is large, quiescent and stores up energy. Sperm, on the other hand is small, actively motile and spends energy. It will be noted that these basic differences in the two opposing initial cells are

characteristic of the average adult male and female in practically all species. In the matter of conduct, for example, everyone is familiar—especially the woman—with man's strenuous pursuit of his objective. Once his interest becomes fixed on his heart's or mind's desire, nothing else matters but its achievement. He moves vigorously toward it, overcoming obstacles at any cost, leaving a trail of wreckage behind. The woman, on the other hand, as man well knows, tends to be static. She is not easily mobilized, and therefore often keeps him waiting. Woman must preserve a safer and more stable situation for the security of the offspring and herself. She not only conserves her own strength but reaches out her hand to stay the man's impetuosity, to retain his energy for the supply and defense of her protectorate. Geddes and Thompson<sup>4</sup> have expressed the same thought by saying that femaleness is correlated with preponderant anabolism, maleness with emphatic catabolism.

This view is supported by Riddle's<sup>5</sup> observations on differential basal metabolic rates between males and females. He found that rates for males were consistently higher than those for the opposite sex. If, then, one accepts the notion that in the extragenital phase of human beings the androgynous differences between man and woman are to be found in their types of body form, their conduct and their mental attitudes, one can proceed to a more detailed consideration of individuals of each sex.

#### ANDRIC AND GYNIC QUALITIES

##### Morphology

Viewed from in front or from behind, the basic silhouettes of the male and female forms can be respectively described as one of angular rectilinear-ity or of curving ovoid. The lateral aspect of the woman presents perhaps less of the ovoid outline, but a greater emphasis on localized curving convexities. From in front, the man's arms appear to be hanging freely dependent from the shoulder points, and at the elbow there is little or no obtuse angle known as the carrying angle. His pelvic breadth is notably narrower than that of the square shoulders, and the lower extremities are straight or slightly bowed at the knee. When the heels are approximated the space between the lower extremities presents a characteristic outline (Fig 1). The inner belly of the gastrocnemius is more prominent than the outer, and the outer curve of the calf bends sharply in toward the external malleolus. In the woman, on the other hand, the shoulders are more sloping, and the upper extremity instead of hanging from the acromion point seems to extend the downward mov-

ing neck shoulder modeling in a continuous curving line. The carrying angle is well marked, so that the forearm and hand clear the prominent outward curve of the hip and thigh, which in turn springs from well above the iliac crest. The far wider hip line is determined in part by the bony structure and in part by the greater distribution of fat over the lower abdominal, pelvic and upper thigh areas. The lower extremities are rounded, and when the heels are together, the thighs are approximated from the crotch to the knees, which are pressed in close apposition. Be-

FIGURE 1 Showing Interspace of the Approximated Lower Extremities in Women (A) and in Men (B)

tween the knee and ankle a space appears, owing partly to the genu valgum and partly to the less emphatic inner belly of the gastrocnemius. The outer line of the leg sweeps in an even, continuous curve from knee to outer malleolus.

Besides these more general contours or silhouette contrasts (Figs 2 and 3), differences of surface modeling between man and woman are well known. In men such observable localized bosses or protuberances as may appear are chiefly due to the well developed muscles, which are covered only by a thin layer of subcutaneous fat. What have been ordinarily designated as secondary sex characters, namely, breasts, mons veneris, girdle and thigh fat deposits, on the other hand, constitute the otherness of a woman's surface modeling. The woman's muscles are not large and knotty, and may be completely hidden beneath a fairly thick, smooth panniculus. The distribution and quantity of facial and body hair constitute another well known set of morphologic criteria that differ between men and women.

### Physiologic Panel

Some physiologic phenomena show andric and gynec differences. Perhaps the most notable of these is the basal metabolic rate, which, as mentioned above, is known to be higher for males than for females. It is also usually accepted that red-cell counts and hemoglobin levels are lower for women than for men. Of this, Riddle<sup>5</sup> states: "... present knowledge establishes the probability

and females can be lowered by prolonged inactivity of the animals, as shown by Lusk and DuBois,<sup>6</sup> but such effects of rest are more striking in the male. As Riddle<sup>5</sup> says, "Any sex changes which may occur as a direct result of prolonged inactivity should be in a male-to-female direction." Child<sup>7</sup> believes that differences in susceptibility to external toxic agents are characteristic features of different levels of physiologic gradients, or

FIGURE 2. Showing Increasing Emphasis on the Gynec Factor in the Male Morphology.

that these excess values [that is, red-cell and hemoglobin] in males cling to maleness because they are a real part of the metabolism machine and because sex difference takes its basis and origin in metabolic difference." Here the oxygen-carrying capacity seems to indicate a connection with the metabolic level, and the pulse rate has usually been said to be higher for women than for men. The notion that metabolic rate and sex difference are closely related has been noted by numerous observers. Furthermore, the rate in both males

more specifically that a relation exists between susceptibility and basic metabolic rate:

With certain qualifications and limitations, it appears to be true that the rate of oxidation is in some degree a measure of the rate of living. It has also been shown that in the less highly specialized protoplasm susceptibility to certain ranges of concentration or intensity of external agents is an indicator of rate of oxidation and may be used as a rough comparative measure of differences in rate. There is, therefore, a real experimental basis for the statement that susceptibility is in general a measure of rate of metabolism or more particularly oxidation.

Thus, all the observations and experiments related to metabolism and sex difference support the notions of the biologists, Doncaster<sup>3</sup> and Geddes and Thompson,<sup>4</sup> that gynec values relate to ques-

findings are interesting and show for example the following generalizations.

Masculinity in men at either of two educational levels is associated with positive interest in active and

FIGURE 3 Showing Increasing Emphasis on the Andric Factor in the Female Morphology. (Figure at Right Illustrates a Case of Gulland Double Adrenal Tumor)

cence and conservation of energy, andric to its expenditure.

#### Psychology

In the psychologic panel, the task of differentiating andric and gynec characters is not altogether an easy one. Terman and Miles<sup>5</sup> undertook to assay the opposing qualities by means of various questionnaires and word-association tests. Their

mechanical pursuits, it is also associated with indifference to artistic and cultural pursuits. Femininity in men is the reverse of masculinity in its relationship to interests. Masculinity in women . . . is associated with positive rather than negative interests, with activity and, in the more highly educated, especially with intellectuality. Femininity in women shows the reverse of masculine trends. It appears associated with less intense positive interests and these are directed towards the arts of home and social life. Mental fem-

inity is expressed also in indifference to active scientific and in the better educated, intellectual interests.

There is, too, in the popular conception of maleness the quality of direction or leadership to which is applicable Murray's<sup>9</sup> term "regnancy." Or it might be called dominance, as opposed to the more commonly presumed feminine qualities of subservience and docility. Intelligence and reason, however, cannot justifiably be classed as essentially male; neither can intuition and emotion be allocated exclusively to women, for all these mental functions are extragenital possessions of every person. Some of these variable qualities no doubt are products of specific hormones. On the other hand, recognizable criteria of a different sort, perhaps conditioned, also seem to enter the picture. Thus, man's traditional notion of woman's nature and hers of his, and what in consequence each may expect of the other in the social and economic structure and in personal relations, inevitably stamp each with a reciprocally accepted cognition of sex. This picture, projected by a woman of what to her is a man, or by a man of what to him is a woman, varies widely in terms of racial, national and cultural background. Indeed, it seems to take on the order of an ethnic trait. Nevertheless, it is possible that from an infinite variety of blendings of andric and gynecic psychic values there may result preponderant projectivity or conservatism, determination or irresolution, directness or evasiveness, brutality or gentleness that will produce well-defined patterns of psychic personality. These may then be correlated with andric and gynecic qualities in the other panels of the total organism. The observable signs of these complete patterns are to be sought, not only in morphology and physiology, but also in the person's attitude toward life and in his manner of merging himself in his constantly changing environment.

#### CLINICAL APPLICATIONS

It was earlier suggested that if, instead of the genital mark, the androgynous mosaic were used as the criterion for division of individuals into sex groups, many of our present sex classifications in medicine might need revision. In this respect, the challenge offered to clinicians by the allocation of diseases according to sex is of greatest interest. There have been numerous studies of this matter; one of the most thorough being that of Mobius.<sup>10</sup> Moreover, in the textbooks of medicine, the paragraph on incidence usually states that the disease in question is commoner in one sex than in the other. After an exhaus-

tive inquiry in which he admits complete inability to explain the occurrence in men of diseases strikingly more frequent in women, Mobius concludes that if it were not for alcohol and syphilis, men would be less often sick and would live longer than women! Notwithstanding this naïve capitulation to a selected stress of environment, however, it should be noted that in his discussion of muscular dystrophies he remarks that muscle is notably "manly tissue; its failure difficult to explain."

That Nature apparently has more use for females than for males has long been known. From start to finish the latter show greater susceptibility to disease and a higher death rate. Thus, for example, studies of the sex ratio indicate that there are 160 early male abortions and 130 male stillbirths for every 100 female ones. Furthermore, at term, there are 104 or 106 living boys for every 100 girls who survive, but at the end of the first year, only 100 boys remain alive for every 103 girls. Bakwin<sup>11</sup> reports that among infants under one year of age 130 to 134 boys die for every 100 girls. This is a sweeping toll, which exists at a time when the genital phase of sex amounts to an almost negligible part of the total sex endowment. One gains the impression that the organismal or androgynous phase of sex must contain some curious relation between andric and lethal forces. One can accept, I think, as a limited factor against a man's chance of survival, Mobius's<sup>10</sup> belief that males are, in general, more exposed than girls and women to hazards, alcohol and syphilis. Also, it is known that developmental anomalies are commoner in males than in females, as though it were more difficult to build a male than a female. Thus, for example, in a series of 2000 cases of pseudohermaphroditism ten to one possessed the male gonad (Mobius). Furthermore, there is likewise that small group of rarer maladies that display the interesting phenomenon of sex linkage. The following conditions reported by Davenport<sup>12</sup> and others are dominant in males and recessive in females: coloboma, color blindness, night blindness, congenital nystagmus, ichthyosis, hemophilia, webbed toes and Gower's muscular atrophy. There remains, however, for further consideration a great group of more or less common diseases that appear year after year in the wards of general hospitals everywhere. Among these, one finds a varying incidence in men and women, changing from an equal distribution to more or less extremes of emphasis in one sex or the other.

Figure 4 charts a group of diseases that have been selected simply on the basis of their differ-

ential frequency in the two sexes. But it should be remembered that the figures are based on the concept of sex in terms only of gonad type. In other words, these are men because the gonad is testicular; those are women because they bear ovaries. The concept of the nongenital androgyny as a constitutional factor has not been introduced. Yet the very nature of the shifting curve apparent in the chart, which moves almost continuously from one sex preponderance to the other, suggests a susceptibility gradient rather than two diametrically opposed sex types. Furthermore, in many cases

there may be other gynec marks of contour, fat distribution, gesture, facial expression and turn of mind. Such men may be adequate sires, thus supporting their claim to masculinity in the genital phase. But in the rest of the organism strong gynec emphasis appears. One might infer from these considerations that as a general principle the more completely a person is differentiated toward maleness or femaleness, the less should be his or her predisposition for those diseases in which the opposite sex factor is a contributing one. Almost the reciprocal of the foregoing situation appears among the subjects of peptic ulcer, an illness in which the sex ratio is high, the ratio of men to women being 5 or 6:1. Here again the afflicted women usually possess evidence of andrie emphasis. It is interesting, too, to note that there is a tendency in ulcer families to produce a preponderance of male offsprings, whereas more female descendants appear in families of gallstone patients.<sup>13</sup>

In alcoholism the sex ratio is also high. Most statistics give the ratio of men to women as 6 or 8:1. But many observers will recall that the impression made by drunken women is a more masculine than feminine one. In my own experience with inebriates, almost every woman presented unmistakable emphasis on andrie characters. Interesting, too, is the fact that whereas for the whole alcoholic series men significantly preponderate, in Korsakoff's psychosis the ratio drops to 2:1. But I have not directly observed such cases in women for the purpose of evaluating the androgynous mosaic. This curious reversal of andrie-gynec emphasis in a special aspect of the human being's reaction to alcohol finds a parallel in rheumatoid arthritis and the spondylitis of Marie-Strümpell. Thus, in the general incidence of rheumatoid arthritis, 3 women are affected to 1 man. But in the cases of spondylitis, the ratio of men to women is 10:1. Heberden's nodes are found almost exclusively in women and, as originally pointed out by the great English clinician, usually at the climacteric. Such a phenomenon no doubt may be considered to be more directly determined by the hormone change (modification or curtailment) than by the original balance of somatic cellular androgyny. The age factor likewise must enter the picture, but much is still to be learned concerning the biologic relation of age and sex.

Gout, on the other hand, is almost entirely confined to the masculine sex. Concerning the androgynous balance of patients with this malady, I have met some difference of opinion. Two of my colleagues tell me that of the few female

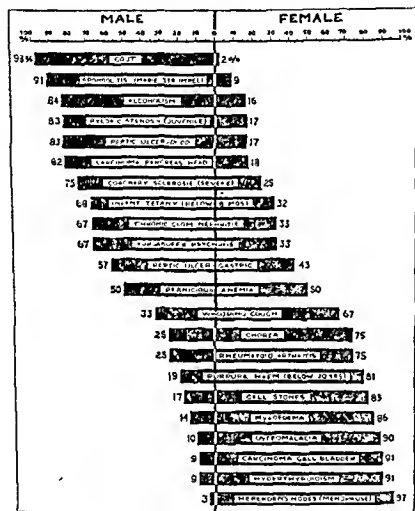

FIGURE 4. Differential Sex Incidence in Disease Susceptibility.

it has been possible to show that persons of one sex who develop a disease commoner in the opposite display notable emphasis on the inappropriate androgynous component of their own.

The scope of this paper does not permit a detailed discussion of each disease shown in the chart so that only two or three will be offered.

The patient with gallstones is one example. It is generally considered that women are more prone to the disease than men, in the proportion of about 5 or 6:1. Moreover there is an old medical saying that the commonest type of woman to be affected is "fair, fat and forty." When, however, a man who is the subject of cholelithiasis appears, one is often struck by the strong emphasis on gynec characters in his total person. In addition to evidences in skeletal measurements

gouty patients whom they have seen all presented strong emphasis on gynec features, with minimal emphasis on the andric. On the other hand, Jamieson<sup>14</sup> refers to Motley's picture of Margaret of Parma, "with her imperious temper, her masculine appearance, her moustache and her gout." It is possible that in my colleagues' cases the andric emphasis was much less marked in the morphologic than in the other panels.

When one attempts to explain the possible significance of disease incidence in relation to androgyny, the notion arises that the nature of the disease may express the different manner of energy manipulation that was earlier associated with each sex. Thus, men are commonly more vulnerable to diseases involving the apparatus for spending energy in action, whereas those that are related to energy storage and resting tissue metabolism arise chiefly in women. From the point of view, then, that sex appears to be a fundamental quality of somatic tissue, apart from its genital purpose, it is possible to contemplate the susceptibility to certain diseases as a further example of such bisexual somatic endowment.

Perhaps this dual possession may also be a mixed blessing. Concerning external agents, no doubt, andric or gynec properties do determine many patterns of reaction to life that are necessary or appropriate for the good of the individual man or woman. In primitive societies, however, the necessity for division of labor between man and woman for the care of offspring called out the opposite characters of each in widely separate spheres of action. All the outgoing energy production of the man was required to provide food, to build his cabin and to fight in defense of his home and family. The woman's energy on the other hand overflowed serenely through the house, surrounding her young with benevolent protection. Her instincts kept the larder jealously stored. Her swift intuition was alert to sense approaching danger; threatening problems were met out of stored experience by a remarkably successful empiricism. At that stage of history, men had comparatively little use for gynec qualities, or women for andric, so far as problems of adjustment to environment were involved. But these more or less unused opposite characters have become valuable to each sex with the increasing mechanization of contemporary civilization. Struggles of man against Nature have given place to those of man against man, and have confronted the individual with new kinds of adaptation demands. More and more, all occupations are being invaded by both sexes. In some of these, women are forced to swing their latent andric

factors into action; in others men must employ their gynec values. Police officers, business executives and lawyers, for example, are callings that attract women whose androgynous mosaic is highly colored with andric emphasis. The culinary art, horticulture, nursing and, finally, the practice of medicine are occupations toward which men lean when their gynec values are well developed. Of these, medicine is one of the most interesting. For many years it has been followed almost exclusively by men. Yet it is quite obvious that much of the success of the physician depends on his gynec values of intuition, understanding and impulse to conserve. It may be because of woman's increasing perception of her latent andric forces in the intellectual field that she now is entering the medical profession in steadily mounting numbers.

The purpose of the foregoing remarks has been to point out that this balancing pair of opposites—an Heraclitean enantiodromia—presents no cause for shame or embarrassment, but rather contains important values for every individual of each sex. Consequently it would be well if each person could recognize his or her androgynous pattern and permit its andric or gynec components to function appropriately in respect to the momentary life situation.

There is, however, a further sphere in which these two powerful forces may interact, not with environment, but on one another within the isolation of the self. Here in the innermost citadel, where the ego strives to preserve its essence, threats to the inviolability of the personal identity are challenged and parried. The intensity of this protective response is often reflected in the most extreme and grotesque compensatory efforts. These result apparently because for the average man there is no threat to self-preservation more potent than the implication of inadequate or declining virility. The notion that feminine qualities are inherent in his personality is one not easily accepted by most men. An excellent example of the early appearance of this sort of emotional distress is that which appears in boys who tend to plumpness and whose external genitalia develop slowly. And it has been my experience that such children never wholly lose the sense of inferiority established in those early days, notwithstanding subsequent achievement of physical and functional genital adequacy. Individual effort, however, to compensate for a deep psychobiologic awareness of essential inadequacy is a matter that is exceedingly difficult to evaluate mathematically. It remains inevitably individual,

an infinite variable. At present, it cannot be brought into the same statistical category with the morphologic and physiologic observations herein reported. But the principle may be illustrated by the effort of a certain soldier in World War I to satisfy himself that he was secure in the biologic sense. He was a congenital eunuchoid whose gracile form displayed the delicate nonmuscular contours of a young girl. He was accepted for service, and soon found himself an infantryman at the Chateau Thierry front. Not content with holding his place in the line, he requested the special duty of messenger between the advanced observation posts and the trenches. This peculiarly dangerous and fatiguing task he performed with distinction. On his return to peacetime occupation in America, the first job he selected was that of a ship loading longshoreman.

Of somewhat similar nature is the interesting observation that a majority of our peptic ulcer patients are drawn from the ranks of taxi cab drivers, policemen and firemen. These occupations demand constant output of energy in aggressive and often dangerous effort. Consequently, it is understandable that all these occupations expose their representatives to inner doubts concerning the validity of their essential beings. The intensity of these doubts may well relate to the actual balance of the andric and gynec forces that is present within the individual, and to his constitutional sensitiveness to the threat of his gynec component. From this conflict arises a fear in the subconsciousness of the potential peptic ulcer patient, for example, that when the crucial test comes he will fail to play the masculine role adequately for the preservation of either his body or his soul (ego?), or both. Now it has been my observation that among these patients the emphasis on the gynec component, especially within the psychological panel, has been unusually high—a paradox of the nature of the employment.

\* \* \*

Thus, it appears that, in respect to external agents, andric and gynec forces possess highly spe-

cialized and harmonizing reaction potentials. But within the person the two factors may come to grips with one another in destructive conflict. The intrinsic male fear is of his gynec component, which, if he could but accept and understand it, might prove instead to be a powerful ally. In view of these considerations, it becomes easier perhaps for each man and woman to appreciate how important to successful negotiation of life relations is an awareness, if not a complete understanding, of the phenomenon of androgyny. No doubt the andric and gynec factors, like other individual endowments, serve a biologic purpose. But depending on a person's repudiation or acceptance of them, they may become the source of destructive conflict or reservoirs from which energy may be wisely released toward creative work and equanimity.

## PNEUMONIA IN MASSACHUSETTS: 1900-1940

DWIGHT O'HARA, M.D.\*

BOSTON

THE advances recently encountered in the treatment of pneumonia have been so spectacular that we have not dared to take our eyes from the road ahead, lest we fail to negotiate another sudden turn. Yet behind us lie facts that must not be forgotten, because they concern themselves with the very road over which we have been traveling, and there is no more useful way to visualize our progress than to retrace the actual path by which we have come. Modern pneumonia discussions have concerned themselves principally with selected groups or selected problems within the larger mass of the people as a whole. This is as it should be, for only by such selection can facts be established in detail. The experience of an entire population as expressed by its mortality figures, on the other hand, may be utilized to demonstrate the mass reaction of millions of people to the respiratory hazards of their environment. Although such experiences must be cautiously interpreted for pneumonia in Massachusetts, it is proper and may be profitable to speculate concerning the degree in which current habits and efforts have influenced the great changes that have taken place. It is especially pertinent to examine these relations while they are still fresh in mind.

To present a simplified concept of our pneumonia experience, the mortality curve for "all forms" of the disease has been chosen for illustration. Although this choice is open to criticism on several grounds, I believe that there is no better index of what has actually been occurring in Massachusetts. Morbidity rates are notoriously unreliable and incomplete. The separation of the lobar pneumonia cases is still accomplished by criteria on which the clinician and the pathologist do not always agree, and probably has more to do with the speed of invasion and the intensity of reaction within the host than with the circumstances of definition. Whether one prefers a clinical, anatomic or even a bacteriologic definition of lobar pneumonia, one will find that its curves pattern themselves very closely after that established for all forms. It is also of interest that the same pattern has been followed by the curves for measles, whooping cough and other

respiratory infections, each of which may appropriately be considered an integral part of the curve for all forms, and to have come under the same influences that have operated on the others. The accompanying chart (Fig. 1) is therefore considered the best available illustration of the behavior of pneumonia—including lobar pneumonia

FIGURE 1.

—in Massachusetts for the present century. In addition, the curves for the registration area of the United States closely parallel this curve.

During the first seventeen years of the century, the pneumonia death rates were relatively constant. The total variation in Massachusetts was less than 15 per cent, and the trend was but very slightly downward. Then the epidemic of 1918 showed on what an unstable basis the relation between the pulmonary system and the outside world rested. The more one looks at this chart the more one appreciates the difficulty of estimating the influence of cause and effect in this disease. Involved explanations are needed to show why other clinics could not duplicate the therapeutic results achieved with unconcentrated serum at the Hospital of the Rockefeller Institute<sup>1</sup> in 1917; why two successive years in a single clinic led to opposite conclusions on the value of serum therapy, as they did on the pneumonia service at the Boston City Hospital<sup>2</sup> in 1920 and 1921; and why the general practitioners of medicine

\*Professor of preventive medicine, Tufts College Medical School; visiting physician, Boston City Hospital.

exhibited seeming indifference to what the enthusiasts of twenty years ago considered the great therapeutic contribution of the day. State-sponsored serum treatment was begun in 1919 in Massachusetts. In the light of what has happened, it is well that serum therapy was not universally adopted at that time, for it would now be difficult to escape a correlation between such an adoption and the very evident change in the mortality trend that took place (Fig. 1).

In the decade between 1920 and 1930, a remarkable series of reductions in pneumonia mortality occurred, reaching a point that was 50 per cent lower than the average of the first two decades. The trend of the curve for these ten years turned so sharply downward that it would, if projected, cross the base line in 1950! Of course the prospect of any such projection is fantastic, but it is important to remember that the major part of the reduction of the last forty years took place in this one decade. Whether the influenza epidemic had removed people with pulmonic susceptibilities, as has been suggested, or whether the general nutrition and resistance of the population were enhanced by changed habits and living standards is mere speculation. Better treatment may have been a factor, but not specific treatment, because very little serum was used in Massachusetts during this period; nor was any other therapeutic method employed on a large scale. One recalls enthusiastic claims for physical, chemical and biologic agents, but none of them enjoyed sufficiently widespread use to be reflected in this experience of the population as a whole. Most clinicians will agree that the therapy of the 1920 to 1930 decade was highly empiric, but that under it pneumonia somehow became a kindlier disease. Comment began to be heard on the mildness of the pneumonia seasons. The florid pneumonias, with full lobar distributions that lasted for a week or more, still occurred, but less frequently, whereas the abortive one-day or two-day pneumonias appeared, or at least were recognized more generally.

After 1930, it was plain that the pneumonia rates in Massachusetts could not continue along the trend that had been established for them following the influenza epidemic of 1918. There were too many people in the older age groups for whom pneumonia was a friend. As Osler<sup>3</sup> said: "Taken off by it in an acute, short, not often painful illness, the old escape those cold gradations of decay that make the last stage of all so distressing." The Massachusetts rates were also already lower than those of most other parts of the country, but as one recalled the explosion of

1918 one had a sense of insecurity. It was like an Indian summer: one was sure that it could not last. It probably would not have lasted if the present effective methods of treatment had not developed in rapid succession.

During the first five years of the Massachusetts Pneumonia Study,<sup>4</sup> from 1931 through 1935, the volume of serum treatment was not high; 793 cases were treated, and the total of pneumonia deaths in the State was 19,309—a ratio of approximately 1:24. During the next two years, 1936 and 1937, serum was given in 957 cases, and the total deaths amounted to 8394—a ratio of 1:8. This was the first period in which anything approaching an effective volume of serum therapy was applied in Massachusetts, and yet this treatment was accompanied by mortality rates that, in 1936 and 1937, were higher than they had been since 1930. This is true both with the figures for lobar pneumonia and with those for all forms. It may mean that the Indian summer was coming to an end in 1936. Those who collaborated in the Pneumonia Study believe that the rates would have been higher still, had not a comprehensive program of serum administration been under way. It therefore seems to be a fair conclusion that in 1936 and 1937 the pneumonia program minimized what might otherwise have been a greater natural variation toward seasons of increased pneumonic severity.

This is a point of more than academic interest, and it should be made at this time before one forgets just what really did happen between the two wars. The major part of the mortality reduction was spontaneous and rapid, and had nothing to do with antipneumonia efforts. It was due to natural causes, if living standards and habits may be included in this category. After 1934, a reaction in the severity of the disease occurred. It would probably have been a greater reaction, had it not been curbed by the gathering power of the pneumonia program. In 1938, with rabbit and other serums for the higher types of pneumococci, in 1939 with sulfapyridine, and in 1940 with sulfapyridine and sulfathiazole, the curve was again brought to new low points.

The rate for 1940, 61.6 per hundred thousand population, is the lowest yet recorded in Massachusetts. The amount of serum dispensed by the State was 40 per cent less in 1940 than in 1939. There is no such accurate measure of the amount of sulfonamide drugs used in 1940, but common knowledge would place its volume well above that of 1939. In other words, the best results were coincident with an increased usage of drug and

a decreased volume of serum treatment. This means that the community as a whole benefited by the large-scale application of a relatively safe and inexpensive and easily administered drug, the exhibition of which did not need to wait for bacteriologic study. The simplicity here implied may be open to scientific criticism, but it remains a practical fact, and suggests that a more effective anti-pneumonic treatment for the population as a whole had been awaiting the discovery of a method that would be simple enough for general application. The application of an involved science is as ineffectual as that of an involved art.

It has been said, "There was a steady drop, year by year, in the deaths . . . since the pneumonia programs began."<sup>5</sup> As an unqualified statement, this is debatable. The mortality record so far does show a steady drop since the use of sulfonamide therapy began. The record also shows that the spontaneous amelioration of pneumonia is the outstanding phenomenon of the century to date. This same natural amelioration is plainly written into the mortality returns for all the air-borne infections, including that chronic one—tuberculosis. Our respiratory security, if we have any, must rest largely on this natural foundation. It is the basis of a better health level for the people as a whole. Its versatility embraces all the air-borne diseases, and its total benefits are manifold. Even after excluding smallpox and diphtheria, which have been artificially prevented, the natural amelioration of the air-borne infections is already contributing a greater share to the prolongation of life than that provided by the almost complete elimination of the enteric fevers. For some reason, this epidemiologic similarity in the behavior of the air-borne diseases has never been commented on. Much has been said of the lessened severity

of scarlet fever, but is its present behavior relatively more benign than that of measles, whooping cough or even pneumonia? Fears are sometimes expressed that the virulence of scarlet fever may return, and we are frequently warned of the next influenza epidemic, being lugubriously reminded that we do not know how to prevent the disease that scourged us in 1918. This is true, but in January, 1941, we had a visitation the virulence of which was, for a few people, fully as deadly as anything that was experienced in 1918. Clinically, malignant influenza was in our midst, just as the so-called "malignant scarlet fever" occasionally still appears, but some natural communal force resisted its spread.

Thus, there is much evidence to confirm a belief that during the present century pneumonia has been increasingly confronted by a collective resistance in the host. Early in the last decade, this resistance stabilized the pneumonia death rates in Massachusetts at a level 50 per cent lower than that of the first decade of the century. The pneumonia program and especially the widespread application of chemotherapy have now contributed to a still further depression of the death rates from pneumonia.

## THE FREQUENCY OF POLIOMYELITIS IN PREGNANCY\*

W. LLOYD AYCOCK, M.D.†

BOSTON

INDICATIONS of the widespread and more or less uniform dissemination of the virus of poliomyelitis are seen in such epidemiologic features as the geographic prevalence and age distribution of the disease; in the gradation from frank to mild or suspected abortive forms of the clinical disease; and in the far more extensive occurrence of subclinical infection, as indicated by the development of serologic immunity in those who do not have the disease in any of its recognized forms.

The limited and selective occurrence of the frank disease indicates that some added circumstance determines clinical or subclinical infection on exposure to the virus. Certain of these selectivities point to differences in the person exposed rather than differences in exposure. A tendency to familial occurrence indicates that susceptibility may be inherent; seasonal and climatic variations in the frequency with which exposure to the virus results in the paralytic disease points to a physiologic function rather than to a fixed anatomic character; the association of the disease with persons of a certain constitutional type is suggestive of endocrinologic differences; the occurrence of poliomyelitis following surgical procedures on the upper respiratory mucosa indicates that temporary mucous membrane conditions may affect susceptibility; and, finally, because of the implication of the upper respiratory mucosa as the portal of entry of the virus, the suspected selectivity seen in the association of poliomyelitis with pregnancy, in view of known mucous-membrane alterations due to estrogenic changes of pregnancy, suggests that autarcologic susceptibility to poliomyelitis may reside, at least in part, in the economy of estrogenic substance.

As is well known, pregnancy affects the development or progress of a number of diseases, either favorably or unfavorably. These effects may be secondary to mechanical influences of the gravid uterus, they may be due to nutritional stresses, or they may result from intrinsic physiologic

changes, more specifically some of the marked endocrine changes of pregnancy. Thus, the improvement seen in certain cases of pulmonary tuberculosis has been ascribed to mechanical effect, such as splinting of the thorax; whereas the severity and fatality of pneumonia are perhaps less

FIGURE 1 Expected Poliomyelitis during Pregnancy in Massachusetts

clearly attributed to immobilization of the diaphragm by the gravid uterus. The added nutritional demands may induce polyneuritis in patients already on a minimal diet, or this deficiency disease may be secondary to hyperemesis. Physiologic changes, including increased blood dilution and volume and increased cardiac output, with decreased hemoglobin, serum protein, non-protein nitrogen and red cells, account for the effects on heart disease. Certain endocrine disorders are initiated by, or are a continuation of, endocrine changes of pregnancy: toxic goiter may be activated, and pituitarism may be influenced. In still other diseases, no satisfactory explanation

is forthcoming for the effects noted. The mechanism of the so-called "therapeutic effect" of pregnancy on syphilis, as well as the resistance exhibited by pregnant animals to experimental infection with syphilis, is unknown. Because of the frequency of association, pregnancy has been regarded by some as an important predisponent to lethargic encephalitis.<sup>2, 3</sup>

The numerical infrequency of paralytic poliomyelitis, especially in view of the fact that the disease is preponderantly one of younger age

pregnancy is less than 1 out of 1000 cases of poliomyelitis, and less than 1 out of 50,000 pregnancies.

In reviewing the literature, 28 cases of poliomyelitis associated with pregnancy have been encountered, and an additional 28 cases have come to notice either by observation or personal communication (Tables 1 and 2). Since these cases have been collected incidentally, no estimate of the frequency of poliomyelitis in pregnancy can be drawn from them. A good many represent individual case reports, and some have been mentioned

groups, makes its chance occurrence in pregnancy small. The average annual occurrence of poliomyelitis in Massachusetts for the ten-year period 1928-1937 was 455 cases, of which an average of 185 cases were in females. The number of births and stillbirths in the same population per year is approximately 76,000. Three-fourths of this number represent an approximation of the number of women pregnant at a given time. On a basis of the age distribution of poliomyelitis and the age of pregnancies, the estimated coincidence of the two conditions, as shown in Figure 1, at any given age is fractional, the total for all ages being 1.3 cases per year. But since this estimate is based on the incidence of poliomyelitis, of which only half the cases were paralytic, it may be seen that the expectancy of paralytic poliomyelitis in

in connection with other studies of the disease. The incompleteness of the record of poliomyelitis in pregnancy is further suggested by the fact that in the literature certain cases diagnosed as the well-known polyneuritis of pregnancy,<sup>20</sup> because of residual paralysis or fatal outcome with respiratory paralysis, possibly were actually cases of poliomyelitis.

The only outbreak in which the frequency of poliomyelitis in pregnancy has been studied was in Detroit in 1939.<sup>21</sup> A total of 528 cases were recorded, of which 255 were paralytic. Four cases occurred during pregnancy. In Table 3 are shown the female population, the estimated number of pregnancies, the expected coincidence of poliomyelitis with pregnancy, and the observed cases in the various age groups. Although this occur-

rence is over four times the expectancy, the number involved is too small to be considered conclusive. But the finding is in line with other evidence presented, suggesting that pregnancy may be one of the predisposing influences to paralytic poliomyelitis.

This suspected selective occurrence is in accord with other selectivities suggesting that susceptibility to paralytic poliomyelitis may reside in a disturbance of some physiologic function, which may be subject to fluctuations in the patient, is endocrine in nature, and is operative through ef-

enhance resistance to intranasal instillation of virus<sup>22-23</sup> It is not known whether, on the one hand, the particular preparation used, the dosage and the manner of administration were sufficient to give changes that could be considered optimal so far as enhancement of resistance is concerned; or whether, on the other hand, such changes are entirely artificial and quite beyond what could be expected to exist naturally. However, since the experimental observations agree with epidemiologic implications, it is believed that the artificially induced conditions may perhaps be

fects on mucous membrane. The known mucous-membrane changes in pregnancy, which are attributed to estrogenic changes, and the experimental production of alterations in the genital and nasal mucosae of monkeys by the estrogens, —because of the implication of the nasal mucosa as the portal of entry of the virus of poliomyelitis, —have formed the basis of two sets of experiments in an attempt to determine the nature of the factor responsible for susceptibility to paralytic poliomyelitis. tests of the effect of artificially induced changes on the susceptibility of monkeys to intranasal instillation of virus, and comparative urinary estrogen assays on poliomyelitic patients and normal persons

The injection of estrogenic substance into castrate immature female monkeys was found to

considered as reflecting conditions of resistance in the natural disease. A small number of comparative urinary estrogen assays have been done on poliomyelitis patients and normal subjects. The results indicate a higher excretion of estrogenic substance in the group of poliomyelitic cases.<sup>22</sup>

The question may well be raised why, if the administration of estrogen protects castrate monkeys, the higher excretion of estrogen found in poliomyelitic cases and characteristic of pregnancy should not confer a similar benefit. No convincing answer can be given. It may be noted, however, that the hormonal status of the pregnant woman differs from that of the nonpregnant, as well as the castrate animal, in a variety of ways. For example, pregnancy is dominated more by the corpus luteum hormone than by estrogen

Pituitary growth-hormone secretion, as well as prolactin, is enhanced during pregnancy. It may be stated, in short, that the end effect of several interacting variables, one of which may be increased estrogen, might actually be different from increased estrogen alone. In this particular case,

the administration of estrogen to castrate animals approaches the latter condition, whereas conditions in the natural disease involve the interaction of a number of hormones, of which increased urinary output of estrogen may be only one manifestation.

### SUMMARY

Seasonal, climatic, familial and constitutional selectivities in the distribution of paralytic poliomyelitis among those exposed to the virus point to differences in the persons exposed rather than to differences in exposure. Bulbar poliomyelitis following tonsillectomy and adenoidectomy, in view of the implication of the upper respiratory mucosa as the portal of entry of the virus, suggests this mucosa as the seat of operation of susceptibility.

Fifty-six cases of poliomyelitis associated with pregnancy are cited, 28 from the literature and 28 from personal records. The time of pregnancy when the disease occurred is unknown in 2 cases. Only 9 cases were recorded in the first trimester of pregnancy, whereas 19 cases were in the second trimester and 23 in the third. Three cases occurred post partum. Thus, the latter months of pregnancy appear to be chiefly concerned, although it must be borne in mind that the data for the first months may be discrepant.

The manner of collection precludes statistical analysis, but it is estimated that the chance coincidence of the two conditions is roughly 1 in

1000 poliomyelitic cases and 1 in 50,000 pregnancies. In a study of the frequency of poliomyelitis in pregnancy in the Detroit outbreak in 1939, the estimated expectancy of coincidence was less than 1 case, and 4 cases were observed. The suspected association with pregnancy, in view of accompanying mucous-membrane alterations due to estrogenic changes, suggests that autarcologic susceptibility to poliomyelitis may reside in the economy of estrogenic substance. Experimental effects of estrogenic substance on susceptibility to intranasal instillation of virus are in accord with this concept.

Because of the difficulty in establishing the significance of numerical frequencies in studies of this sort, the present report is intended to raise the question of the frequency of poliomyelitis in pregnancy, in the hope that similar studies will be made in other outbreaks.

## CLINICAL NOTE

AN ELASTIC CHEST GIRDLE  
FOR RIB FRACTURES\*

HAROLD G. LEE, M.D.†

BOSTON

THE treatment of fractured ribs by adhesive strapping is so generally accepted, and on the whole is so satisfactory, that I have hesitated to report a retentive chest girdle used in treating such injuries. However, since for several years the girdle has proved to be a more comfortable form of treatment than the conventional strapping, as well as a more efficient means of immobilizing the chest, it seems to have special value. The girdle also has the advantage of being adaptable to cases in which the use of adhesive strapping is definitely contraindicated.

The idea of using a girdle to immobilize rib fractures is not new, although this form of treatment has received little recognition, and the use of the girdle has tended to be limited to those cases in which adhesive strapping is objectionable. Immobilizing belts and girdles of various designs and materials have been recommended by Knowles,<sup>1</sup> Funston,<sup>2</sup> Hammond,<sup>3</sup> Waugh,<sup>4</sup> Welti<sup>5</sup> and Christensen.<sup>6</sup>

In our clinic, the girdle is used in the treatment of all fractured ribs. When more than a single rib is broken, the position is maintained by increasing the width of the binder. The use of the girdle solves the problem of treatment when burns or abrasions are associated with the fracture, when the patient has a hairy chest or a tender skin, or when the respiration is embarrassed.

Patients find the binder extremely comfortable, and they promptly return to work. No pain is experienced on movement of the thorax, and there is no feeling of constriction, such as that when adhesive strapping is used. The man who does heavy work may tighten the binder during the day and loosen it at night. Immobilization is

assured, because there is no tendency for the girdle to slip, as there is with adhesive strapping.

A more detailed description of the elastic girdle than that given in Figure 1 is hardly necessary. In width, it varies from 10 to 20 cm., depending on

FIGURE 1. Elastic Girdle Applied to Chest.

the number of ribs fractured. The girdle is easily and quickly made from readily obtainable material, and it costs very little. It is easily fitted, since the elasticity and the long range of buckling space allow for adjustment to a chest of any size. In its application, it should be tightened until there is no pain on forced inspiration or expiration. Because of the ease of adjustment, the girdles may be made in advance and kept on hand. When sufficient healing has taken place to ensure immobilization at the site of the fracture, the girdle is gradually loosened, and finally removed.

## MEDICAL PROGRESS

## DIABETES MELLITUS

ELLIOTT P. JOSLIN, M.D.,\* HOWARD F. ROOT, M.D.,† AND C. CABELL BAILEY, M.D.‡

BOSTON

## STATISTICS

THE death rate for diabetes in the United States reached 25.6 per 100,000 in 1939, with a total of 33,395 cases, thus exceeding 23.8, the previous highest figure, which was attained in

TABLE 1. *Deaths per 100,000 Population from the Chief Causes of Death in the Registration Area of the United States in 1939, as Compared with the Figures for the Same Causes in 1938 and 1900.\**

DISEASE	1939		1938		1900	
	RANK	RATE	RANK	RATE	RANK	RATE
Heart disease	I	276.1	I	268.9	IV	132.1
Cancer	II	117.8	II	114.6	VIII	63.0
Cerebral hemorrhage	III	88.0	IV	85.7	VII	71.5
Nephritis	IV	83.1	V	77.2	V	89.0

1938. One death in 41.5 was assigned to diabetes. In 1938, diabetes ranked ninth as a cause of death, but by 1939 it displaced premature births and became eighth. The positions held by diabetes in 1900, 1938 and 1939 are shown in Table 1. It requires little imagination to see that diabetes will soon displace tuberculosis and pneumonia, and then it will be exceeded only by arteriosclerosis in the heart, brain and kidneys, and by cancer and violence. Yet this very growth in incidence may detract from its recognition, because so few diabetic patients die of their disease that other diseases—which are complications or coincidental, like cancer and tuberculosis—may claim recognition before it and displace diabetes as the primary cause of death. Private clinics may therefore be the chief source in the future of reliable statistics on the disease. For statistics on diabetes, the seventh edition of Joslin, Root, White and Marble's<sup>1</sup> book on the treatment of diabetes mellitus presents recent data in considerable detail.

All articles in this series will be published in book form, the current volume is *Medical Progress Annual, 1940* (Springfield, Illinois: Charles C. Thomas Company, 1941 \$4.00).

\*Medical director, George F. Baker Clinic, New England Deaconess Hospital.

†Associate in medicine, Harvard Medical School, physician, New England Deaconess Hospital.

‡Fellow in medicine, New England Deaconess Hospital.

The number of new cases for the year 1940 is estimated at between 50,000 and 60,000 by Mr. Herbert H. Marks, of the Statistical Department of the Metropolitan Life Insurance Company.

The remarkable alteration in the age distribution at death of diabetic patients in the United States for the last twenty years is shown in Table 2. There were approximately only one fifth as many deaths in the first decade of life in 1939 as in 1919, one fourth in the second and third, one third

in the fourth, three fifths in the fifth, and six sevenths in the sixth; not until the seventh decade are deaths now more numerous. Conversely, there were 33 per cent more deaths in 1939 in the tenth decade, nearly 80 per cent in the ninth decade and 60 per cent in the eighth decade.

The median age at death of patients with diabetes in New York City is advancing. Between

TABLE 3. *Median Age at Death of Diabetic Patients in New York City.*

PERIODS	MEDIAN AGE AT DEATH			
	MALES		FEMALES	
	Lowest	Highest	Lowest	Highest
1904-1921	56.1	59.1	58.2	61.0
1922-1940	59.2	64.7	60.4	65.4

1904 and 1921, inclusive, and between 1922 and 1939, inclusive, there was a significant change equivalent in range to three to five years for men and two to four years for women, owing largely to the introduction of insulin (Table 3).

For 927 deaths occurring, in the experience of Joslin, Root, White and Marble, between January 1, 1937, and March 29, 1940 (the Hagedorn Era), the average age at death was 64.8 years, and the duration of the disease 12.5 years, in contrast with 46.7 years and 6.1 years, respectively, for the period June 1, 1914, to August 6, 1922 (the Allen Era).

The total number of persons with diabetes in New York City is estimated to be somewhere between 50,000 and 75,000, or 6.8 to 10.2 per 1000 population.

In a systematic study based on reports of the physicians of the Berlin Medical Society, Umber and his associates<sup>2</sup> report that in the population of Berlin (4,346,074) there were 14,153, or 3.2 per 1000, diabetic persons—in 1916 in Charlottenburg, the estimate was 2.3 per 1000. Insulin was used in the treatment of 37 per cent. The necessity of supplying insulin to diabetic patients to increase their working capacity has been stressed by Umber's group. In the diabetic clinic of the West End Hospital in Berlin, only 3 per cent of patients were unable to work on account of their disease. The number of Jews in Berlin was estimated at 82,788, and among them 3.5 per 1000 were diabetic; insulin was used by 43 per cent.

### EDUCATION

The present is the Era of Education in diabetes. Two large monographs on diabetes have recently appeared, along with an increasing number of schoolbooks, textbooks and manuals for patients. Camps for children are far more numerous, exceeding eighteen in number, and probably are more largely attended. The number of articles on diabetes, whether clinical or experimental, is so voluminous that a reviewer is swamped and sometimes almost breathes a sigh of relief to see a periodical that has nothing related to diabetes on its pages.

Boards of health are increasing their diabetic activities, and in New York City last winter more than two hundred popular talks on the disease were sponsored by the Board of Health, in co-operation with medical societies. For some years, Cincinnati has been particularly active in this regard. In New York City many years ago, Dr. Charles F. Bolduan was largely instrumental, working from his position in the Board of Health, in bringing about, with the help of the New York Academy of Medicine, the organization of the New York Diabetes Association.

More instruction in diabetes is given in hospitals. More nurses are engaged in teaching diabetic patients, and more classes have been organized

for their benefit. In addition to this work for patients, more time is set aside for the study of diabetes in nurses' training schools and in medical schools.

Insurance companies have a vital interest in diabetes. This year, one of them has undertaken an educational program that is nationwide in scope and on a broader and yet more detailed basis than has ever before been attempted. It is evident that the interest not of one but of many insurance companies is being awakened. Their accurate statistical methods are sorely needed in diabetes. It would be even more valuable if they made a searching inquiry into the deaths reported as diabetic and the deaths of persons who earlier were known to have had diabetes.

For several years in England, there has been an organization for diabetic patients known as the Diabetic Association. It issues the *Diabetic Journal*,\* sold for a shilling, which contains practical articles on diabetes suitable for patients and the public. The association and the *Journal* continue to function despite the war.

During the last few months, the American Diabetes Association has been incorporated, its first meeting was held in Cleveland last June preceding the meeting of the American Medical Association. This society is national in scope and is best described by Articles II and III of its constitution:

**ARTICLE II Purpose** The objects of this association are (1) to disseminate among physicians information relative to the diagnosis and treatment of diabetes by means of meetings, bulletins and the publication of papers in scientific journals, and through a central office, which would at all times make available information concerning various aspects of diabetes, (2) to educate the laity in the early recognition of diabetes and in the realization of the importance of medical supervision, (3) to secure and co-ordinate the active co-operation of associated groups acceptable to the Trustees in the educational and organizational phases of the association, (4) to make and publish statistical surveys of diabetes, (5) to encourage and support clinical, experimental, sociological and statistical studies by means of grants, (6) to encourage the adequate treatment of diabetes and the establishment of summer camps for children.

**ARTICLE III Membership** The membership of the association shall consist of four classes: (1) active members, (2) associate members, (3) honorary members, (4) corporate members. Only active members in good standing shall have the right to vote. Any physician with proper qualifications may be elected an active member of the association by a majority vote of the Trustees. Active members shall pay stipulated annual dues. All those interested in the aims and purposes of the association, whether physicians, scientists, statisticians, dietitians, nurses, social workers or laymen, may become associate members upon election.

\*The *Journal* is published quarterly at 124 Baker Street, London, W. 1.

by the Trustees, and upon payment of stipulated annual dues. Honorary membership may be conferred by the Trustees on those individuals who have rendered distinguished services in medical or other fields related to diabetes. Associated medical or welfare organizations, civic or educational groups and insurance companies may be elected to corporate membership of the association in recognition of the auxiliary services which they may render to the association.

### *The Prevention and Cure of Experimental Anterior-Pituitary Diabetes*

In last year's review,<sup>3</sup> reference was made to the unpublished work of Haist, Campbell and Best,<sup>4</sup> of Toronto, and of Lukens and Dohan,<sup>5</sup> of Philadelphia, on the prevention and cure of the experimental pituitary type of diabetes of the dog and cat. To recapitulate briefly, Best and his co-workers found that when insulin was injected into a dog at the same time as anterior-pituitary extract, diabetes failed to appear, and no destructive changes occurred in the islands of Langerhans; Lukens and Dohan observed in a cat with experimentally produced diabetes, even of five months' duration, that hydropic degeneration, the incipient diabetic lesion, which had appeared in the island cells, was reversible, and the diabetes could be cured with insulin. Cure in the cat was related to the peculiar persistence, characteristic for that animal, of the hydropic degeneration.

Dohan, Fish and Lukens<sup>6</sup> report two dogs resistant to the injection of anterior-pituitary extract, but following partial pancreatectomy without associated glycosuria, permanent diabetes resulted as soon as a small amount of extract was administered. Two other dogs were made permanently diabetic after sixty-two and ninety-eight days of treatment with small but fairly constant doses of extract. In dogs made diabetic with anterior-pituitary extract, the diabetes may be so severe that 85 per cent or even more of the available glucose of the diet is excreted in the urine, but if these dogs are treated with insulin, the rate of progress of the diabetes seems to be inhibited.

The blood glucose in dogs with moderate and severe pituitary diabetes, sixteen to twenty-four hours after the last feeding, varied widely and showed little relation to the proportion of the available glucose of the food excreted in the urine. It appeared to be a poor index of the severity of the diabetes.

The concentration of serum fatty acids was above normal in the severer cases of diabetes, being particularly marked in dogs excreting 90 per cent of the available glucose of the diet. There was no correlation between the quantity of ketonuria and the concentration of the serum fatty

acids in individual determinations. The withdrawal of insulin combined with fat or meat feeding resulted in a marked increase in the concentration of serum fatty acids. The cessation of insulin treatment with fasting was associated with very little change. Meat feeding, in comparison with that of fat, brought about a marked ketogenic effect.

Some animals did not show permanent recovery with insulin treatment. These cases were associated with infections, poor control of the diabetes by insulin or the institution of insulin treatment after more than five months of diabetes.

In last year's review,<sup>3</sup> it was considered that the prevention and cure of the experimental disease were attained primarily by the use of insulin, which permitted rest to the pancreas by the removal of excessive metabolic strain. Subsequently, however, Best and his co-workers<sup>4</sup> not only confirmed the previous observation of Housay that the hyperglycemic effect of anterior-pituitary extract was not obtained in fasting dogs, but also noted that the feeding of fat had a similar effect in thwarting the action of the diabetogenic factor in the extract. Fasting and the feeding of a high-fat diet are not only reminiscent clinically of the fasting era of diabetic treatment introduced by Allen and of the high-fat diets advocated by Newburg and Marsh in this country and by Petrén in Sweden, but also corroborative of their rational employment as therapeutic agents.

Still more recently, Lukens and Dohan<sup>5</sup> have added another means to the three already known—insulin, fasting and high-fat diet—to be effective in the prevention and cure of experimental diabetes, and with its discovery have afforded an explanation of the action of each of the four. This fourth measure is the use of phlorhizin. Phlorhizin does not decrease the sugar in the urine or indeed the production of sugar, but actually lowers the sugar in the blood by removing it. For the four procedures, a normal—that is, a low—blood sugar represents the greatest common divisor. And here again support is found for the persistent, aggressive and, one might add, orthodox treatment of diabetes originally advocated by Naunyn. We consider the clinical effects of this work far reaching.

Cantilo,<sup>7</sup> in the Argentine, has treated 40 diabetic women in the menopause with large doses of sex hormones, to influence the diabetogenic factor in the pancreas. He considers that he obtained a constant improvement of the state of all who showed evidence of disturbed hormonal balance, as shown by hyperpituitarism and as measured by the dextrose-tolerance test. He empha-

sizes the need of separating the climacteric from the usual type of diabetes. Successful responses were obtained only with large doses of estrogen and progesterone. Conversely, the use of androgens has been reported as lowering carbohydrate tolerance,<sup>8</sup> and Dr F P Pyles, of Brazil, in a personal communication, refers to a patient whose usual tolerance for 300 gm carbohydrate was lowered to about 100 gm while 25 mg testosterone propionate was being taken.

A pancretotropic as well as diabetogenic factor exists in the anterior portion of the pituitary gland, and it has even been suggested that the former by stimulating the islands to secretion might explain why, in the production of anterior pituitary diabetes, signs of recovery are repeatedly manifest in the early steps of the injections. Collip<sup>9</sup> has offered evidence on this point, using a primary alcoholic extract of anterior pituitary tissue. Marks and Young<sup>10</sup> could not confirm his work. Although there is such a factor, they found that it was not identical with prolactin or with gonadotropic, thyrotropic or glycotropic substances. Indeed, they surmise that this principle is not a hormone. Lawrence and Young,<sup>11</sup> by experiments on diabetic human beings and on dogs permanently diabetic with pituitary extract, also failed to confirm Collip's views.

Young<sup>12</sup> attempted to answer the question whether the treatment of an animal with large doses of estrogen would inhibit the liberation from the anterior lobe of the pituitary gland of certain specific hormones and thus influence the course of diabetes. He used dogs made diabetic by injections of anterior pituitary extract. The administration of large doses of estrone, estriol and diethylstilbestrol to four pituitary diabetic dogs and one that had been depancreatized exerted no obvious antidiabetic action. In fact, with estrone and estriol, the effect was prodiabetic rather than antidiabetic. Young discusses the fact that his results are in disagreement with some earlier results of other authors.

These negative attempts to isolate a pituitary hormone that will offset the diabetogenic pituitary hormone have been failures, but it seems well worth while to continue the search. Haist, Campbell and Best<sup>4</sup> write: "The hope is raised that proliferation without degeneration, produced by the administration of anterior pituitary extract along with adequate amounts of insulin, may lead to an increase in the islet tissue and a more nearly normal islet fraction." Indeed, Marks and Young<sup>13</sup> have recently shown that certain anterior lobe extracts increased the insulin content of the rat's pancreas to almost twice normal values.

Encouraged by the reports of the Toronto and Philadelphia laboratories in preventing diabetes in a dog and curing it in a cat, McDaniel, Marble and Joslin<sup>14</sup> reviewed their cases in the hope of finding clinical evidence of prevention or cure. They sought these in the group showing hydropic degeneration of the islands. In human beings, however, fulminating diabetes is infrequent, and it is especially rare to have a fatal case since the introduction of insulin. Warren<sup>15</sup> had only 22 cases of hydropic degeneration among 486 autopsies on patients with diabetes. Light of these and a later case were from the George F. Baker Clinic. They included 2 patients carefully treated with a relatively or extremely low carbohydrate diet and insulin who died, we should now say needlessly, of diabetic coma, 1 with coma brought on by hyperthyroidism, 2 in whom cancer entered into the picture, destroying a portion of the pancreas, 3 with infections and 1 with an uncertain duration who died suddenly in coma. Among the cases with a sudden onset, cures were not found in children whose diabetes was not recognized until they were in coma, in prepubertal and adolescent children, in women whose diabetes began in pregnancy or in the menopause, and in the large group of elderly diabetic patients, although some cases of unusual improvement were observed. Yet the search did disclose hints that made the authors urge still more aggressive, active and consistent treatment of the disease with the reduction of carbohydrate and the use of insulin.

#### ACIDOSIS AND FAT METABOLISM

Certain recent experiments have discredited four of the former basic concepts of fat metabolism and ketogenesis.

First, Knoop's<sup>16</sup> hypothesis of successive beta oxidation, which he described in 1904, has been discarded, and in its place Hurler's<sup>17</sup> hypothesis of multiple alternate oxidation of the fatty acid chain, in which simultaneous oxidation occurs along the entire chain at alternate carbon atoms with the formation of ketones, has been accepted.

Secondly, the ketone bodies, which were formerly considered to be toxic and unavailable for use in the body, have now been shown by Chaikoff and Soskin,<sup>18</sup> Friedemann,<sup>19</sup> Stadie, Zapp and Lukens<sup>20</sup> and others to be the normal end products of fatty acid oxidation and to be utilized in the peripheral tissues by both normal and diabetic subjects. It is only when the ketone bodies accumulate owing to the excessively rapid breakdown of the fatty acid molecules—as in diabetic acidosis, when insulin is inadequate—that the

ketones form more rapidly than they can be utilized and have a toxic effect, because their acidic properties disturb acid-base equilibrium, electrolyte balance and water exchange.

The third revolutionary change is the discarding of the old idea that ketones can be oxidized only by obligatory coupling with carbohydrate oxidation. The experiments of Barker<sup>21</sup> with depancreatized dogs and of others show that fat may be completely oxidized without coupling with carbohydrate oxidation.

The fourth hypothesis—that fatty acids are converted into glucose in the liver—was disproved by the experiments of Stadie, Zapp and Lukens<sup>20</sup> with liver slices of diabetic cats.

At present, Stadie<sup>22</sup> believes that part of or all the fatty acids catabolized undergo a preliminary partial oxidation in the liver to acetoacetic or beta-hydroxybutyric acid. These ketone bodies can be used without chemical coupling with carbohydrate oxidation. He also believes that during exercise the utilization of the ketone bodies keeps pace with their increased formation.

Stadie further believes that the greater the carbohydrate metabolism, the less the fat metabolism.

By actual analysis of total bodies of mice, MacKay and Drury<sup>23</sup> showed that ten times as much of the carbohydrate fed was stored as fat than as glycogen. Fat is ordinarily the great energy reservoir of the body. Drury<sup>24</sup> holds that one of the actions of insulin is to facilitate the formation of fat from carbohydrate and thus to store carbohydrate in its most efficient form.

#### TREATMENT

The need for adhering to adequate standards of treatment and control of diabetes is still to be emphasized. Hyperglycemia and glycosuria, as well as acetonuria, are abnormalities that the most seasoned students of diabetes have always sought to correct. As Allen<sup>25</sup> points out, hyperglycemia must denote an insulin deficit, because it is absent in normal persons on identical diets. In the management of diabetes in children, Jackson, Boyd and Smith<sup>26</sup> based their treatment on the premise that physiologic levels of control (normal blood-sugar levels, freedom from glycosuria or insulin shock, and completely adequate diet) are desirable and attainable. It must be admitted, however, that their children remained for comparatively long periods in the hospital. Evidently, in the series of 800 cases described by Smith and Grishaw,<sup>27</sup> standards of treatment and control were orthodox. In a group of 247 obese diabetic patients, the disease was moderately severe in 79 and mild in the remainder, but when reduction in weight was established, the number of moderately severe cases became 32.

Present-day tendencies in dietary treatment seem to be definitely in the direction of moderation with respect to the total amount of carbohydrate fed. Thus, the New England Deaconess Hospital diets containing 140 to 175 gm. of carbohydrate are certainly more commonly used than diets with 200 gm. or more. Our experience has clearly indicated that a smaller dose of insulin is thus required, and that the tendency to hypoglycemic reactions is less. Dr. Allan M. Butler,<sup>28</sup> at the Children's Hospital in Boston, also favors the lower carbohydrate diet and gives an excellent table showing a parallel between the amount of carbohydrate in the diet and the amount of insulin required in diabetic children.

#### CONSTANCY OF ACTION OF PROTAMINE ZINC INSULIN

The constancy of the action of protamine zinc insulin is emphasized by Ricketts,<sup>29</sup> who showed that its effect when injected once every twenty-four hours is relatively constant, regardless of the time of day the injection is given. The best criterion for the proper dose is the fasting blood sugar, because protamine zinc insulin metabolizes endogenous carbohydrate. Supplementary crystalline insulin is often necessary before one or two of the daytime meals. Errors in the use of crystalline insulin should never occur, since the only form of crystalline insulin manufactured at present exerts an action that is rapid and comparable with regular insulin, but is not to be compared with the long action of protamine zinc insulin, histone insulin or globulin insulin. In general, most young patients and many with moderately severe diabetes need both crystalline insulin and protamine zinc insulin. A careful comparison of various methods of using these two forms of insulin is given by Watson,<sup>30</sup> and the conclusion is reached that the best results were obtained by the use of two types of insulin, separately injected.

#### ESSENTIAL FRUCTOSURIA

The importance of essential fructosuria lies in the fact that it is a harmless anomaly of metabolism sometimes mistaken for diabetes and therefore resulting in dietary restriction and the use of insulin in patients in whom neither is required. Lasker<sup>31</sup> has analyzed 40 cases in the literature and added 7 cases of her own. Apparently, this disorder is inherited as a Mendelian recessive, commonly found in the brothers and sisters of patients, but usually absent in the parents. It is essential to remember that fructose may be formed from dextrose in an alkaline urine by the process of chemical inversion. This can happen in a diabetic urine or a urine containing bacteria. Also,

in cases of deficient liver disease, fructose may be excreted in the urine after a test dose of sugar.

anism favoring the early and excessive development of arteriosclerosis.

#### ADVANTAGES OF EARLY DIAGNOSIS AND AGGRESSIVE TREATMENT

The advantages of the early diagnosis and aggressive treatment of diabetes lie in the preservation of a high tolerance. The point is well made by Dr. F. D. W. Lukens, who writes in a personal communication:

Diabetes has commonly been treated by diet with the least restriction possible, and then by insulin used as late as possible and in the smallest doses possible to control the metabolism. This may be called the principle of minimal treatment. It appears to be fairly suitable for the management of diabetes of long duration, but *at the time of first diagnosis*, at least if soon after onset, a different policy might well be adopted, namely, *early maximal treatment*. The feature underlying this method is that as soon as the diagnosis is made insulin should be given in the largest doses which can be tolerated without reactions. The advantages to be anticipated include: better education of the patient from the beginning; more prompt and complete control of the disease and its progress (by resting the pancreas?); and the possibility of preventing the condition from becoming permanent. The prevention of permanent damage to the pancreatic islands has not been demonstrated in man, although recent results in two laboratories show that this is possible in early experimental diabetes. It may be that well-equipped clinics will strive for such prevention in human beings albeit with the most sober expectations.

#### ARTERIOSCLEROSIS

The coexistence of arteriosclerosis with diabetes, particularly the occurrence of the severe form of occlusive arterial disease in patients in middle life and in diabetes of long duration, is an outstanding problem. Whether the excessive degrees of arteriosclerosis develop prematurely because of uncontrolled diabetes, or whether the tendency is due to an inborn, inherited trait, is still discussed. As a practical problem, it still remains true that the responsibility rests on every physician who treats diabetic patients to give appropriate instruction and treatment to avoid the accidental development of serious lesions, which may often be prevented from reaching a serious stage if early treatment is given. A valuable contribution is a recent account from the laboratory of Dragstedt. Dragstedt and his co-workers<sup>22</sup> found arteriosclerosis of the aorta in 11 depancreatized dogs, an incidence of 13 per cent. In 75 normal dogs, the incidence was 5 per cent. They noted that the dogs were given insufficient amounts of lipocaic to maintain normal fat metabolism, and they pointed to the disturbances of fat metabolism in the liver in diabetes as the mech-

#### INSULIN RESISTANCE

Extraordinary cases of resistance to insulin requiring doses of 1000 to 3000 units a day continue to appear. We<sup>23</sup> have observed two cases—those of a young clergyman and a nurse—in both of which, rather rapidly in the course of a few weeks, such a resistance developed that 2000 units of insulin were required; during the next year, the resistance gradually disappeared. In a case reported by Hart and Vicens,<sup>24</sup> a sixty-year-old Hungarian fruit dealer developed a general, as well as a local, allergic reaction lasting four days after the first dose of insulin. During the next few days, the insulin dose reached the maximum of 920 units. However, the insulin resistance disappeared within a few weeks, and subsequently the patient required no insulin at all.

In certain cases, allergy to insulin requires desensitization. The rapid method of desensitization by the injection every twenty to thirty minutes of very small doses, beginning with 1/100 unit and rapidly working up to several units in the course of four to six hours has been successfully used, but the method we have adopted in several recent cases and prefer has been to begin with 1/1000 unit and increase by 1/1000 unit at each dose before the three meals and on retiring; before breakfast 1/1000 unit, before lunch 2/1000 unit, before the evening meal 3/1000 unit and on retiring 4/1000 unit; occasionally, one can go ahead more rapidly. Patients who begin insulin and then omit it are especially prone to allergic complications.

Another case of severe insulin resistance in a patient with diabetes and chronic lymphatic leukemia is reported by Levi and Friedman.<sup>25</sup> This patient received 4000 units of insulin a day for four days, and 19,900 units over a period of five successive days. His white-cell count varied from 61,000 to 25,000. The possibility that in the large number of leukocytes a trypsinlike ferment was responsible for anti-insulin action was suggested. In a study of carbohydrate metabolism in 4 cases of insulin resistance by Root and Carpenter,<sup>26</sup> it was striking that in 2 cases, when glucose was given to the patient in the fasting state, almost no increase in the respiratory quotient was obtained. Yet with levulose the rise in the respiratory quotient within thirty minutes to an hour was practically equivalent to that found in normal persons. The highly specific character of the metabolic defect is as yet unexplained. In

these 4 cases, the striking feature was the cyclic character of the phase of insulin resistance.

### VITAMIN DEFICIENCIES

The place of vitamin deficiencies in diabetes continues to excite interest and to stimulate experiments. Brazer and Curtis<sup>36</sup> report a study of 20 patients with juvenile diabetes mellitus, all of whom were found to have poor light adaptation as shown by the Frober-Faybor biophotometer. The daily administration of 60,000 units of vitamin A in the form of fish-liver oil brought about a return to normal, whereas the use of crystalline carotene failed to bring about improvement. In discussing the various causes and explanations of these symptoms, they accepted the inability of the patient with diabetes to convert carotene to vitamin A. This seems to depend on some deficiency in liver function. That there is any specific relation between vitamin deficiencies and the causation of diabetes is still very doubtful. Owens, Wright and Brown<sup>37</sup> have confirmed earlier studies in finding that the administration of ascorbic acid to diabetic patients produced no change in the severity of the diabetes.

The relation of the peripheral neuritis of diabetes to vitamin deficiency is still somewhat uncertain. In a series of 422 ambulant diabetic patients, Fein, Ralli and Jolliffe<sup>38</sup> found 9 who had a symmetrical peripheral neuropathy similar to that found in patients who suffered from proved vitamin B<sub>1</sub> deficiency. The findings that served as a basis for diagnosis consisted in sensory changes in the lower extremities, such as hyperesthesia, tenderness of the calf muscles and loss of position sense and of vibratory sensation, beginning first in the toes and later extending upward, in addition to absence of ankle jerks. The daily administration of thiamine by mouth resulted in cure of 8 subjects and improvement in 1. Some adjustment in the insulin dose went on at the same time, and hence it is possible that diabetic treatment, as well as thiamin, played a part in relieving the condition. Indeed, the exact place of thiamin in the polyneuritis of alcoholism, pregnancy and even beriberi has been questioned by Meiklejohn.<sup>39</sup> He points out that the laboratory animals suffering from thiamin deficiency do not have a true peripheral neuritis but do have a disturbance of the metabolism of the central nervous system. His belief is that, when a true peripheral neuritis occurs, the treatment should include an ample and nutritious diet together with the administration of yeast and crude liver extract to

ensure an adequate supply of vitamin B complex. In the treatment of the neuritides associated with diabetes, when a vitamin deficiency is suspected, it is probably wise to use the complete vitamin B complex rather than thiamin alone.

One of the features of diabetic neuritis is the existence of an increased amount of protein in the cerebrospinal fluid without an increase in cells. This condition is characteristic of the Guillain-Barré syndrome or polyradiculoneuritis. A series of 15 cases of this type is described by de Jong.<sup>40</sup> In these cases, the total protein in the acute stage varied between 125 and 412 mg., with an average of 214 mg. for 100 cc. The average cell count was 6. The patients were quite young, the average being twenty-two years. The onset was rather sudden, and recovery occurred usually after an average of eight weeks. Slight infections had been present at the beginning in some cases. These cases differed materially from the diabetic cases that one sees clinically. Ordinarily, in diabetic patients, the onset is insidious, and in a fully developed case a young person's recovery frequently requires more than eight weeks. However, in severe cases, development of atrophy and contractures and a long duration of the neuritis were signs akin to what we see in diabetic patients. The fatal cases had bulbar involvement and respiratory failure.

### CASE 27371

#### PRESENTATION OF CASE

A fifty-nine-year-old woman came under medical observation with the following story.

Twenty years previously, the patient had been treated for peptic ulcer, without recurrence of symptoms, and about this time she suffered a transient attack of thyrotoxicosis, which was treated with x-rays. The details of the latter illness were not available. Ten years later at the time of the menopause, she became mentally unstable, with symptoms referable to the gastrointestinal tract and heart and "a good deal of jointiness." For this illness, she visited several sanatoriums. Six years before, the patient had suffered from regurgitation of food shortly after eating, and at this time it was found that the heart was enlarged and that the liver extended two fingerbreadths below the costal margin; the latter was not tender, and the upper border reached the fifth rib. X-ray studies revealed a slightly enlarged heart and tortuous esophageal folds, with some delay at the cardia, but no varices could be demonstrated. The basal metabolic rate was +13 per cent. Approximately one year later, the patient suffered a transient attack of pleurisy, and for twenty-four hours a left pleural friction rub was audible. She carried on in fair health for four years, and during this time she was considered by successive physicians to be a neurotic patient whose regurgitation of food was not based on organic esophageal disease. Her insistence that she had heart trouble was denied by all. She complained of a good deal of "jointiness" in her hands, and these symptoms were thought to be due to degenerative arthritis, with hypertrophic changes at the joint margins, but no x-ray films were taken to prove this point.

However, for the summers of the previous three years, she had had "mosquito bites" which developed on the dorsal surfaces of the forearms, the jaw line of the face, and along the collar line near the sternoclavicular junctions. These lesions began as tiny, reddish, slightly elevated areas on which there soon developed a central scab. They itched, and the scab pulled off when scratched, leaving a small pit. The erythematous area widened to about the size of a dime, or even a quarter, with a large necrotic area

in the middle. These lesions disappeared in the course of four to six weeks, leaving a depressed white scar, with punctate areas in the scar that probably represented the site of hair follicles. Sometimes at the end of this period, after feeling somewhat giddy for several days, the patient suddenly developed "a lump between her breasts," and a sense of pressure aggravated by breathing and by lying flat or on the left side. This symptom was accompanied by mild nausea and inability to relax, and precluded sleep. It disappeared by morning but recurred the next day for a few hours. The patient had also noticed some shortness of breath on exertion. She had lost 15 pounds, and there was a stare to the eyes, with lidlag. The left border of the heart was 10 cm. from the mid-line in the fifth left interspace, and the first sound was described as "mushy," with a shuffling systolic blowing murmur. The heart beat was regular at a rate of 70, the pulmonic second sound being greater than the aortic, and at the lower sternum a scratchy sound was heard in systole that was believed to be extracardiac; the blood pressure was 144 systolic, 85 diastolic. The liver was palpable two fingerbreadths below the costal margin on deep inspiration, with its upper border at the fifth rib. Neurologic examination was negative. The skin lesions were present, but only in the form of depressed atrophic scars, no fresh lesions being noticed. The patient ran a low-grade fever for one week. X-ray films of the colon and gall bladder, as well as a Graham test, were negative; at the lower end of the esophagus a delay in passage of the barium was noted, with possibly some thickening of the mucous membrane, but it was not the picture of cardiospasm or cancer. Degenerative changes were present about the joints. An electrocardiogram revealed moderate left-axis deviation, with T-wave changes that were possibly due to digitalis or a combination of digitalis and coronary disease. The basal metabolic rate was +34 per cent.

A month later, repeated readings of the basal metabolic rate gave figures of +28, +39 and +36 per cent, so that the patient was given iodine, and in a few weeks the reading was +17 per cent. There was no palpable goiter or evidence of a sub-sternal gland by x-ray examination. Blood counts were normal, the sedimentation rate was high normal, and the stools were normal. The patient carried on for the next four months, gained 7 pounds and remained mentally well; she had very little regurgitation of food, but there was still some exertional dyspnea. At the end of this period, a sensation of weight developed in the anterior chest, and shortness of breath increased. On examination, she did not appear ill, but a to-and-fro

friction rub was heard over the precordium, base and apex, loudest over the left sternal border at the fourth interspace. The heart was regular at a rate of 96, with the same systolic murmur, and the pulmonic second sound was greater than the aortic; the blood pressure was 130 systolic, 90 diastolic. The liver was three fingerbreadths below the costal margin. The white-cell count was 8000, and the sedimentation rate 40 mm in one hour. An electrocardiographic recording showed marked left-axis deviation, a PR interval of 0.22 second and a QRS complex of .09 second,  $T_1$  and  $T_2$  were upright,  $T_3$  inverted, and  $T_4$  flat. The temperature had risen to 100°F. forty-eight hours later, but fell to normal in the next two days, and by this time the precordial friction rub had disappeared. The patient was kept in bed for one month, then gradually allowed up, but it was noted that the neck veins were distorted in recumbency, that there was an increase in dyspnea, and that a nonproductive cough occurred after meals and when the patient was lying in bed. She went to the country at this time, and within a week or two began to develop the aforementioned erythematous skin lesions. The patient's condition remained essentially unchanged for the next two months, at the end of which a rolling heave was observed over the precordium, which was transmitted to the liver region. The liver reached a point five fingerbreadths below the costal margin, but was not tender, the spleen could not be felt, nor were there other signs of congestive failure. Examination of the urine and blood was negative. Salycan produced a diuresis, but did not appreciably affect the exertional dyspnea or cough. A few weeks later, crackles were audible at the lung bases, more pronounced on the left; there was no visible or palpable pulsation of the liver.

On examination, the patient was well developed and well nourished, tired and weak, but mentally clear, with moderate exertional dyspnea, however, she appeared only slightly ill, and the temperature was normal. The cervical veins were distended; there was slight exophthalmos, but the thyroid gland was not enlarged. The fingers were thick and shiny, and the skin showed many small white scars and a few fresh, reddish, scabbed maculopapules on the hands, forearms, face and anterior neck. Examination of the heart showed enlargement to the left, with a normal rhythm at a rate of 80 and a bifid apical impulse. The pulmonic second sound was greater than the aortic, and there was a diastolic murmur at the apex and lower end of the sternum. The pulse was normal, the arterial walls soft, and the blood pressure 140 systolic, 95 diastolic. Persistent fine rales

were present at both lung bases, but no dullness. The liver was enlarged and tender, reaching four fingerbreadths below the costal margin; there was no peripheral edema. Examination of the urine and blood was negative. An electrocardiographic recording showed a normal rhythm at a rate of 80, and a PR interval of 0.24 second; there were low voltage of the QRS waves, flattish T waves and a deeply inverted  $T_1$ .

The patient was confined to bed and given vitamins, digitalis, weekly mercurial diuretics, a normal diet and limited fluids. She improved, but cardiac reserve hung in the balance, with gallop rhythm at the apex, pronounced accentuation of the pulmonic second sound and jugular pulsation. During the next few weeks, the patient had less respiratory difficulty and gained in strength, but new umbilicated papules appeared on the face and arms, edema of the legs developed, and the liver was palpable at the umbilicus. At the end of seven weeks, a protodiastolic gallop was heard maximally at the lower end of the sternum, and there were rales at the lung bases, the liver was firm and slightly tender, and had receded to the costal margin; new skin lesions appeared, the older ones becoming scarred. The urine contained an occasional hyaline cast with a trace of albumin, the blood was normal, with a sedimentation rate of 30 mm. in one hour. Within three weeks the patient began to lose ground appreciably; she developed anorexia, cough, increasing dyspnea and arthritis of the finger joints, and the temperature rose to 101°F. On examination, the fingers were spindled, and new skin lesions were present on the face, arms and legs. The heart findings were unchanged, rales were present at both lung bases, and the liver again reached the umbilicus. Gradually, edema increased in severity and grew more widespread, involving the hands and face; no longer was there response to mercurial diuretics, and jugular pulsation was visible to the ears. The patient became weak, her hands and feet were cold and purple, and the pulse was rapid and feeble, the temperature dropped to 95°F, and albuminuria increased. Occasionally, a curiously loud first or second heart sound could be picked up. Fresh pruritic skin lesions continued to develop and appeared as raised, gray-white, dry, scaly areas measuring up to 4 mm in diameter and surrounded by purplish margins, the whole averaging 1 cm. in diameter.

Terminally, there was little stupor, and death occurred quite suddenly, with deepening cyanosis, approximately six years after the discovery of cardiac enlargement. Fever was present almost daily for the last five months of life.

## DIFFERENTIAL DIAGNOSIS

DR. WALTER BAUER: Being, as Dr. Mallory knows, extremely interested in lupus erythematosus disseminatus I find it very difficult to get away from a diagnosis of that disease in this case. True, the patient was somewhat older than such patients usually are. However, we know it does occur at this age. Over a six-year period, this patient suffered from pericarditis, pleurisy, a recurring rash and, finally, arthritis. It is very difficult to say what caused the joint symptoms. They may have been due to degenerative joint disease. I believe that the patient suffered from mediastinopericarditis rather than simple pericarditis. The former is rare in disseminated lupus, but there are on record three cases that have had a well-defined mediastinopericarditis. There is no mention made in this record of whether she had a paradoxical pulse.

DR. MYLES P. BAKER: She did not.

DR. BAUER: Or whether the heart was fixed in position.

DR. BAKER: It was not.

DR. BAUER: And there is also no mention whether x-ray study showed anything but upward displacement on inspiration.

DR. BAKER: That was not looked for.

DR. BAUER: One wonders if the first episodes in this patient's history could not be accounted for on the basis of the same disease. I took the liberty to ask Dr. Aubrey O. Hampton whether the x-ray findings in the esophagus could be accounted for on the basis of mediastinitis. He stated that he did not know. In mediastinitis, "a rolling" of the esophagus is usually observed. I do not know whether the esophagus in this case showed such changes.

DR. BAKER: I should say not.

DR. BAUER: Dr. Hampton said there was nothing about the x-ray picture to lead one to suspect cardiospasm or intrinsic disease of the esophagus. This patient never had a Broadbent sign?

DR. BAKER: No.

DR. BAUER: One would think she would have had distention of the neck veins as the disease progressed.

DR. BAKER: I did not look for that.

DR. BAUER: The pleurisy could, of course, have been a manifestation of disseminated lupus. The recurrent rash each summer is very suggestive of disseminated lupus. There is one case on record of a patient who had recurring skin rash every summer for ten years except one and that was the year when he worked nights instead of days. There is another case on record of recurring skin

rash for four successive summers, with complete disappearance in between. Another point in favor of this diagnosis is the fact that some of the skin lesions left scars. The arthritis that developed terminally could have been a manifestation of the disease. Whether the original joint symptoms were related to this final illness, one cannot say. One might ask if it is not unusual to see pericarditis as the first sign of the disease. The answer is that it is unusual. However, visceral manifestations may be the first evidence of the disease, and we have seen one patient who had chronic crippling arthritis for ten or twelve years before developing skin lesions. Another had chronic arthritis for a period of four or six years before visceral symptoms became evident. Many of the classic findings may be absent. I think the distribution of the skin lesions in this case is consistent with the diagnosis. The patient had no evidence of the bone-marrow involvement that is sometimes seen in this disease, nor did she exhibit purpura. The absence of leukopenia should not disturb us, because only 30 per cent of our 65 cases had low leukocyte counts.

The patient never developed hypertension. The terminal urinary findings could be explained on the basis of mediastinopericarditis, which I believe she had. Should one consider the possibility of pericarditis from other causes? Did she have Pick's disease of tuberculous origin? One could explain the skin lesions, which resulted in scarring, on the basis of tuberculosis. It would, however, be extremely difficult to explain the arthritis in this manner.

One must mention periarteritis nodosa. It commonly causes pericarditis, which may be associated with mediastinitis. Some of the other findings observed in this case would not be so readily explained by this diagnosis, although we must admit that an additional case of periarteritis nodosa could have all the findings presented by this patient, including the arthritis. We have seen one patient with periarteritis nodosa with a marked synovitis. In this case, the typical vascular lesions of periarteritis nodosa were demonstrated in the synovial blood vessels. A primary vascular disease such as periarteritis nodosa of six years' duration would probably have affected the vessels of the pericardium, heart, cerebrum, abdomen or legs at some time during the course of the disease.

One might suspect rheumatic fever. The PR interval was prolonged—0.22 and, finally, 0.24 second. However, the skin lesions were not those of rheumatic fever. Rheumatoid arthritis can involve serous surfaces, but there seems little reason for seriously considering it in this case.

I consider disseminated lupus the best explanation.

tion of this patient's symptoms and physical findings. One might argue that mediastinal involvement is not in keeping with this diagnosis. However, I know it can occur. Therefore, I believe we were dealing with a patient whose mediastinopericarditis was part and parcel of the picture of disseminated lupus. Tuberculosis need not be seriously considered. Although periarteritis nodosa is a distinct possibility, I believe we can exclude it.

DR. TRACY B. MALLORY: Does anyone care to hazard a diagnosis or express an opinion?

DR. BAKER: This woman presented the picture terminally—indeed, during the last five months—of febrile illness and progressive right-sided heart failure, with accentuation of the pulmonic second sound, a finding that was difficult to explain. We believed that she had disseminated lupus, and in retrospect I doubt very much that she had a thyrotoxicosis. She had always had prominent eyes, with lidlag. I think that an elevation of the basal metabolic rate has been noted in disseminated lupus, presumably in a case in which fever was not prominent. I suspect we were on the wrong track in attributing an elevated basal metabolic rate to recurrent thyrotoxicosis. The difficulty as I saw her from day to day was how to explain the right-sided heart failure that was obviously taking her to her end. I could find no reference in the literature of disseminated lupus to right-sided heart failure, no definite description of myocardial disease that would account for such a picture. We considered the accentuated pulmonic second sound—the loudest heart sound—as evidence of chronic cor pulmonale.

DR. EDWARD F. BLAND: One could explain that with mediastinopericarditis.

DR. BAKER: But would one expect the meager heart sounds and the pronounced gallop rhythm?

DR. BLAND: I do not see why they need be anything more than evidence of a failing heart.

DR. BAUER: I do not see why an accentuated pulmonic second sound must necessarily be indicative of right-sided heart failure. Was she a slender person?

DR. BAKER: No, she was not.

DR. BLAND: I should be inclined to discount the finding.

DR. BAKER: What of the gallop rhythm?

DR. BLAND: It is a good sign of weakened myocardium, either on the right or left.

#### CLINICAL DIAGNOSES

Acute disseminated erythematosus.  
Cardiac failure.

#### DR. BAUER'S DIAGNOSIS

Lupus erythematosus disseminatus.

#### ANATOMICAL DIAGNOSES

Disseminated lupus erythematosus (probable).  
Idiopathic pulmonary endarteritis (Ayerza's disease).

? Periarteritis nodosa of pulmonary vessels.

Polyserositis: pericarditis, pleuritis, peritonitis.

Cor pulmonale.

Infarcts of lungs.

Healed pyelonephritis, slight.

Arteriosclerosis, aortic and coronary.

Lymphadenopathy, axillary.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: The post-mortem examination showed a polyserositis. There was turbid fluid in one pleural cavity. There were some old but loose adhesions and some extensive fluid in the pericardium, and there was 150 cc. of turbid fluid—a small amount—in the pelvic portion of the peritoneal cavity. The heart was hypertrophied, weighing 450 gm., but all the hypertrophy was on the right side, an extreme grade of cor pulmonale. The right ventricle measured from 7 to 10 mm. in thickness, and since it was also markedly dilated, that represents as marked hypertrophy of the right ventricle as I have ever seen.

DR. BAUER: The patient had left-axis deviation, according to the electrocardiogram.

DR. MALLORY: I am sorry about that, but I have no explanation to offer. The lungs were fixed whole by injection of formalin into the bronchial tree. Later, they were examined by means of numerous cross-sections. When the surfaces of these sections were examined under the dissecting microscope, it was apparent that every small artery was markedly thickened, many having no visible lumen, whereas the large arteries showed numerous and large plaques of atheroma. On microscopic examination, we found ordinary but severe atheroma of the large and intermediate-sized pulmonary arteries and more puzzling changes in the pulmonary arterioles. In many places, this was a fibrous, intimal thickening, sometimes evidently the result of thrombosis, organization and recanalization. In some arteries, fresh thrombi were still apparent. In others, the picture was more suggestive of an endarteritis. However, there were a significant number of vessels in the lungs in which the picture was still different. The media of these arteries was thick and necrotic. There was a periaarterial granulomatous process with polymorphonuclears and numerous monocytes, and the picture in these vessels was indistinguishable from periarteritis nodosa.

So far as the rest of the body is concerned, not a diseased arteriole was found, except for some

ordinary atheromatous changes in the heart and in the uterine vessels. The spleen was normal in size. The liver was considerably enlarged and deeply congested, with some central necrosis. The kidneys weighed 350 gm., a little larger than normal. There were a few patches of sclerosed glomeruli, a few dilated tubules filled with hyaline casts and a few lymphocytes suggestive of a very mild healed pyelonephritis. There were also, I think, a few glomeruli showing focal glomerulitis. Whether one could separate those entirely from the old pyelonephritis and attribute them to another process, I am not sure.

Most of the lymph nodes of the body were not enlarged. On external palpation, we did not feel any, but on dissecting into the axillas, we found on both sides a great many enlarged nodes, wet, pink and highly vascular. On microscopic examination, they showed great increase in blood vessels, and necrosis of the germinal centers, changes that we usually find in acute disseminated lupus.

Although a few vessels in the lung were characteristic of periarteritis nodosa, nothing else in the body favored that diagnosis; there were a number of clinical and a few anatomic points that fit better with the diagnosis of lupus.

## CASE 27372

### PRESENTATION OF CASE

An eighteen-year-old single primipara was referred to the hospital three weeks after delivery.

Two months before admission, the patient presented herself at the prenatal clinic of another hospital, where her condition was followed until the time of delivery. She had no untoward symptoms, and physical examination revealed nothing abnormal except minimal ankle edema; the blood pressure was 100 systolic, 80 diastolic, and the urine was normal. During the last six weeks of pregnancy, she gained 11 pounds, and at the time of the delivery was recovering from a cold. Three weeks before admission to this hospital, her child was born after a normal six-and-a-half-hour labor aided by an episiotomy, although it was stated that the patient lost slightly more blood than is usual. On the second post-partum day, the ankle edema was the same, but the face became pallid and puffy. The blood showed a red-cell count of 2,400,000 with a hemoglobin of 48 per cent, and a white-cell count of 16,000 with a normal differential. A Fouchet test was negative. The blood pressure was 100 systolic, 64 diastolic, and the urine was normal. The next day, edema was more marked, and the liver was palpable two fingerbreadths be-

low the costal margin and was somewhat tender. A catheter specimen of urine was strongly positive for albumin, had a specific gravity of 1.015 and contained many white blood cells; colon bacilli were cultured. The nonprotein nitrogen of the blood serum was 100 mg., the uric acid 14 mg., the cholesterol 181 mg., and the sugar 69 mg. per 100 cc.; the icteric index was 5. On the third and fifth post-partum days, transfusions of 500 cc. of blood were given. On two occasions intravenous injections of 100 cc. of 50 per cent glucose were given for anuria. The urine volume rose from less than 400 cc. to more than 1000 cc. The fluid intake was forced to 2000 cc., and the edema increased. At no time did the temperature rise above 99°F. During the eight days before admission, the white-cell count dropped from 35,000 to 21,000. The lochia was foul and persistent, but the uterus was said to have involuted satisfactorily with the aid of two courses of Ergotrate. Finally a small mass developed just lateral to the umbilicus between the lower edge of the liver and the fundus. The edema had slowly increased.

Four months before admission, the patient was in bed for five days with tonsillitis. Her physician painted her throat, and recovery was satisfactory. There was a history of occasional nocturia of several years' duration. The patient's menstrual periods had always been normal. The family history was irrelevant.

On examination, the patient responded slowly and was cyanotic and orthopneic. There was pitting edema of the entire body. She preferred to lie on her right side, her breath coming in shallow gasps, with occasional coughing. The tongue was dry, and there were sordes on her lips. The left arm was much smaller than the right and showed a large ecchymosis above the elbow. The trachea was slightly deviated to the left. Examination of the lungs revealed dullness, increased vocal fremitus and bronchial breathing over the entire right chest. Slight dullness was present at the left base, but the breath sounds were vesicular, with no rales. Examination of the heart showed the left border to be 1 cm. to the left of the mid-clavicular line. The sounds were somewhat distant, with occasional extrasystoles and an inconstant gallop rhythm; the blood pressure was 90 systolic, 68 diastolic. The abdomen was distended and edematous, and shifting dullness was present. The liver was palpable three fingerbreadths below the costal margin. The fundus of the uterus reached a point 3 cm. above the symphysis pubis. Pelvic examination revealed a septic perineorrhaphy, oozing pus. The uterus was in second-degree retroversion, enlarged and slightly fixed. The vaults

were clear. The pupils were dilated, but reacted to light and accommodation. The fundal vessels showed slight narrowing. Examination of the nervous system was negative.

The temperature was 102°F, the pulse 90, and the respirations 30.

Examination of the urine showed a specific gravity of 1.026 and a ++ test for albumin; the sediment was "loaded" with white blood cells and contained an occasional granular cast. A culture grew abundant colon bacilli. Examination of the blood showed a red cell count of 5,000,000 with a hemoglobin of 13.5 gm. (photoelectric-cell technic), and a white-cell count of 21,000, with 82 per cent polymorphonuclears. The nonprotein nitrogen of the blood serum was 63 mg. and the serum protein 4.6 gm. per 100 cc.; the chlorides were 914 milliequiv. and the carbon dioxide combining power 16.5 milliequiv. per liter. A serum van den Bergh was biphasic and slightly above normal. A vaginal smear was negative for beta-hemolytic streptococci; a throat swab showed a few colonies of beta hemolytic streptococci.

An x-ray film of the chest showed a large amount of fluid on the right side and less fluid on the left. The outlines of the diaphragm and heart were obliterated by the fluid. Nothing could be said about the size of the heart or the condition of the lungs. A flat abdominal film showed marked enlargement of the soft tissues of the abdominal wall, consistent with edema. The psoas shadows were poorly outlined, the kidneys incompletely visible. There was an unusual stripy appearance of the abdomen, perhaps due to edema in the retroperitoneal tissues, which accounted for the poor demonstration of the kidney and psoas shadows.

An electrocardiographic recording showed normal rhythm, with a rate of 90 and a PR interval of 0.15 second. T<sub>1</sub> was flat to inverted, T<sub>2</sub> and T<sub>3</sub> were inverted. There was slurring but no abnormality of the QRS complex.

On the day of admission, the right chest was tapped on two occasions, and yielded 250 cc and 800 cc of slightly cloudy, straw-colored fluid. This fluid had a specific gravity of 1.011, contained 3300 red blood cells and 58 white blood cells per cubic millimeter, clotted in five minutes on standing, and yielded no growth. After this procedure, the patient was more comfortable. On the second hospital day, the temperature was 100.5°F, the white cell count 12,000, and the blood pressure 100 systolic, 60 diastolic. An electrocardiogram showed auricular premature beats with a rate of 85 to 90 and a PR interval of 0.19 second. There was slurring of the QRS complex and moderate right axis deviation. T<sub>2</sub> was diphasic,

T<sub>3</sub> inverted. The next day, the patient was placed in an oxygen tent, remained uncomfortable, but was apparently holding ground. The blood pressure dropped to 70 systolic, 45 diastolic. Despite five blood transfusions of 500 cc. each and general supportive measures, the patient rapidly failed, with steadily increasing edema, cyanosis and dyspnea. Death occurred on the sixth hospital day.

#### DIFFERENTIAL DIAGNOSIS

DR FULLER ALBRIGHT "A Fouchet test was negative," whatever that is.

DR. TRACY B. MALLORY The reagent is a mixture of trichloroacetic acid and ferric chloride, which is a strong oxidizing agent and turns bilirubin green. The test is usually applied to urine.

DR. ALBRIGHT. I should like to be sure that the urine was normal in all other respects on the second post partum day. If so, it would rule out many things. One must always remember that specimens can be mixed.

The fact that the liver was apparently enlarged is not particularly significant because of the relaxed abdominal wall from the recent pregnancy.

The anemia was controlled by transfusions.

"A throat swab showed a few colonies of beta-hemolytic streptococci." It would be much more interesting to know whether it was negative for pneumococcus.

I have listed seven things that I shall consider, but only the last two do I consider very seriously. The first is post partum eclampsia. The patient did not have hypertension. I do not think it was eclampsia. The second thing is a colon bacillus pyelonephritis. She was sick on the second day after delivery, and the urine was said to be normal at that time. If that was true, she was not sick because of pyelonephritis. Besides, there is not so much albumin in the urine with pyelonephritis, and her course was much too rapidly downhill for uncomplicated pyelonephritis, and I rule it out as the primary disease. I do not believe that she died of colon bacillus pyelonephritis or septicemia. The next possibility is pneumococcal pelvic infection, with secondary nephrosis, for which one can make a fairly good story. Again, if the urine was normal on the second post-partum day, it would rule out this diagnosis. The patient did have the nephrotic syndrome—at least, a great deal of albumin, a low serum protein with ascites, fluid in the chest and generalized pitting edema. Accordingly, one can make a fairly good story for pneumococcal infection somewhere, leading to nephrosis and ending with a gradual "petering-out." It is too bad that we do not know

whether there were pneumococci in the culture. The fourth condition is acute glomerulonephritis. That was apparently considered also by the person who took care of the patient. I think we can rule it out. There were no red cells in the urine, and the rest of the picture was not particularly characteristic. Then one comes to the question, Did she have a cardiac condition? In favor of that was the enlarged liver. She had a certain amount of edema, a gallop rhythm and a fall in blood pressure, and one wonders if she had massive pulmonary infarcts, with a failing right ventricle. She did have right-axis deviation at one stage, but I do not believe that she had massive pulmonary emboli. There was no particular etiology for cardiac disease. She might have had pericarditis as the cause of the electrocardiographic changes, but that was probably not the diagnosis. The electrocardiographic changes can be explained by the edema of the skin, and do not necessarily indicate cardiac disease. I shall say that the patient did not have, primarily, cardiac disease. I do not believe they would have given the case to me if she had had. One of the more probable diagnoses is a hepatitis of some kind. People do get liver disease after pregnancy. She did have an expanding liver, and a peculiar mass on the right (?) side. She had a low serum protein, which would go with it, and a strange sort of exit, which does not show on the chart. She died with a fairly normal-looking chart, as so many patients with severe liver disease do, but the serum van den Bergh was not impressive, nor was there enough bilirubinuria for hepatitis. I do not believe that she died of toxic hepatitis. That is a diagnosis one might consider more seriously, however. The ecchymosis may have been indicative of vitamin K deficiency and severe liver disease.

The one diagnosis I really am hoping it may turn out to be is terribly far fetched. We know that patients who have severe hemorrhages at the time of delivery and who go into shock are prone to develop infarcts of the pituitary glands and resulting Simmonds's cachexia. We have had three such patients in the Ovarian Dysfunction Clinic. Could this patient have had this? From her red-cell count, it is apparent that she lost a large amount of blood at the time of delivery, following which she ran a rapidly downhill course. The blood chemical findings were quite extraordinary, and I think more attention should have been paid to them in the treatment. Both the serum chloride and the serum carbon dioxide combining power were lowered, each by about 10 milliequiv. per liter. Since these are both anions,

and since the sum of the anions in the serum equals the sum of the cations, we can infer either that the patient had an accumulation of some other anions in her serum or else that her cations were correspondingly low. The most likely possibility is that she had a low serum sodium. This would suggest an adrenal insufficiency or possibly adrenal insufficiency secondary to pituitary disease, that is, Simmonds's cachexia. Of course, the high nonprotein nitrogen and the high uric acid fit in with acute adrenal failure. Against the diagnosis of pituitary infarct, of course, is the general anasarca. I never heard of a patient with Addison's disease or Simmonds's disease who had general anasarca.

In conclusion, if the patient has any endocrine disease, I believe it is Simmonds's cachexia, with a terminal urinary infection. My second choice is liver disease. My third choice is pneumococcal infection with nephrosis.

DR. MALLORY: Are there any other suggestions?

DR. PAUL D. WHITE: May I say a word about the electrocardiogram? I think it is unlikely that edema alone would have such a preponderant influence on the T waves. It may have a striking influence on the total voltage of both QRS and T waves, but there are possible factors behind the edema such as renal or adrenal insufficiency that could change the T waves to this degree without necessarily any intrinsic heart disease or blaming the anasarca. What do you think, Dr. Sprague?

DR. HOWARD B. SPRAGUE: I wondered why the right-axis deviation developed.

DR. WHITE: That was only on the first occasion and was slight.

#### CLINICAL DIAGNOSIS

Acute glomerular nephritis with edema.

#### DR. ALBRIGHT'S DIAGNOSES

Pituitary infarct, with Simmonds's cachexia.  
Terminal urinary infection.

#### ANATOMICAL DIAGNOSES

Acute pyelonephritis.  
Nephrosis?  
Thrombophlebitis of uterine veins.  
Multiple pulmonary infarcts.  
Septic thrombosis of right auricle.  
Anasarca.

#### PATHOLOGICAL DISCUSSION

DR. MALLORY: Dr. Albright is safe in one regard, I am sorry to say, because the pituitary

gland was not examined, so that I can rule Simmonds's disease neither in nor out. We did, however, find a good deal wrong in various other organs. The most striking lesions were in the kidneys, which were considerably enlarged, and contained multiple small abscesses especially numerous in the left kidney. The pelvis of the left kidney was inflamed, and there was also a severe hemorrhagic cystitis. The question might be raised whether it was a hematogenous infection or a retrograde infection. I should say that it was definitely hematogenous, but the process still lies within the group of processes that we lump together as pyelonephritis. The theory of retrograde infection has rather disappeared in recent years, and we consider the vast majority of these cases to be hematogenous. The next question to come up is whether there was anything besides pyelonephritis. The glomeruli were perfectly normal. The tubules showed a very distinct swelling of the tubular epithelium and the presence of enlarged albuminous granules. The picture is not much beyond what is ordinarily called cloudy swelling, which may be found as the terminal stage of many febrile illnesses, but on the other hand, it is perhaps just a little bit beyond it and one might be justified in suspecting a nephrosis. If so, it was considerably masked by the severe pyelonephritis.

The right auricle contained a thrombus that appeared septic, both grossly and microscopically. The condition could be called, I think, an auricular endocarditis if one wished. The direct smears and cultures, however, failed to show organisms or growth. Thrombi in the uterine veins also suggested sepsis. There was massive edema, and each pleural cavity contained over a liter of fluid. There was 150 cc. of fluid in the pericardium.

The abdomen contained considerable ascitic fluid. The liver was not enlarged, weighing only 1300 gm., and this again is an example of a rather small liver readily felt in a patient who has ascites.

DR. WHITE: Was the pleural fluid clear?

DR. MALLORY: Yes; the lungs were also very wet.

DR. WHITE: Did the myocardium show any involvement?

DR. MALLORY: Not that of the ventricles. Beneath the septic thrombus in the auricle, there was some inflammation.

A PHYSICIAN: What was the mass described in the clinical findings?

DR. MALLORY: It may have been the gall bladder, the wall of which was edematous and thickened. Nothing else was found to account for it.

DR. ALBRIGHT: What was the cause of death?

DR. MALLORY: I think it is difficult to be sure of the mechanism of death. I should be inclined to think it was respiratory embarrassment from large amounts of pleural fluid and pulmonary edema. The patient certainly had infection too, but cyanosis was spoken of repeatedly in the course of the record.

DR. BERNARD M. JACOBSON: Do you think it was a fairly acute pyelonephritis coming on a few weeks before delivery?

DR. MALLORY: I should have to guess from the autopsy findings that the pyelonephritis was the chief cause of death. I cannot rule out the possibility of some degree of nephrosis as well, but I should like to make one diagnosis, and that would be pyelonephritis.

DR. ROBERT E. GLENDY: Were there abscesses in any of the other organs?

DR. MALLORY: No.

## THE ROSE OF NO MAN'S LAND

FOR two years, we have been told how different this war is, but as we prepare to defend ourselves and as we watch the British facing its realities, we realize that some of the alleged differences have been purely imaginary. One of the most wishful thoughts has been that man power would not be needed—that this was to be a war of machines. In certain branches, this may be partly so, but in the medical services it is not. One after another, we see the familiar lacks and inadequacies facing us again. It makes little difference whether a man is wounded on a battlefield or in a wheat field or at his desk or in his bed—he must be the recipient of the very best medical and surgical care that can be devised under the circumstances. Preserved blood and serums may replace gum

acacia and salt solutions, and tetanus toxoids may replace antitoxins, but medical and surgical services will be more than ever in demand.

It is thus not surprising that the nurse—dramatized in the other war as the “rose of no man's land”—is again coming into such demand that she must soon be vigorously recruited if our national supply is not to fail us in the coming crises. Fifty thousand well-educated young women have already been called for by the Surgeon General of the United States Public Health Service to avert “serious damage to the Nation's health during the present emergency.” These young women, by entering the already established schools of nursing in our civilian hospitals,—particularly if they are well educated,—can soon relieve staff nurses who are already fully trained and who are already in demand, at least for the nurse-corps reserves of the United States Army and Navy.

In addition to enrolling approximately 600 reserve nurses per month, the Army at the present time has nearly 6000 nurses on active duty and anticipates an authorized quota of 8237 nurses for the fiscal year of 1942. The Surgeon General of the Navy has stated: “The Navy Nurse Corps has now approximately 700 nurses on active duty, including nearly 140 reserve nurses. There are more than 1000 reserve nurses awaiting a call to duty, and this number may be increased by an additional thousand or more by the end of the year.” Practically all such nurses must come from those now in civilian nursing duties, and it can accordingly be seen just where the shoe is going to pinch.

If we are to keep abreast of military and civilian nursing requirements, these 50,000 young women must be enrolled for the fall term in accredited schools of nursing. Surgeon General Parran has stated, “An especial effort should be made to enlist the interest of young college women in this important field, inasmuch as the greatest demand is for nurses who have had a superior education.” Under Dr. Parran's direction, the States Relations Division of the United States Public Health Service is administering a recent congressional appropriation of \$1,250,000, which will facilitate the

training of additional nurses, presumably in the schools of nursing already established and accredited

Even more than in the last war, young women as well as young men are actively challenged. Again, we begin to visualize some of the difficulties to be faced by those who will be charged with keeping "the home fires burning," for the depletion of our civilian nursing services is inevitable. Energetic action to recruit nurse trainees on an emergency and patriotic basis is in order now. If the use of machines—x ray, electrocardiographic and so forth—is doubled in the medical and surgical services of this war, the use of man power and woman power must be tripled.

### SALVATION ARMY APPEAL

THE Greater Boston Annual Maintenance Appeal of the Salvation Army will begin on September 16 with a dinner at the New England Conservatory of Music. Scores of volunteer leaders and workers will assist in raising the \$200,000 that is the goal for 1941-1942.

In the corps cities of Cambridge, Chelsea, Everett, Malden, Medford and Somerville, separate campaigns will be directed to collect the amount set for this year. The quota assigned to the thirty-two towns in which the Salvation Army does not conduct corps organizations is \$40,000.

The Salvation Army, which maintains more than thirty institutions that care for the needy, merits the support of all members of the community. It is hoped that physicians in particular will respond generously, as they have in previous years, to this appeal for help.

### MEDICAL EPONYM

#### KAHN TEST

The precipitation test for syphilis that has attained the widest use in this country is that proposed by R. L. Kahn (b 1887), of the Michigan Department of Health, in his paper, "Simple Quantitative Precipitation Reaction for Syphilis," which appeared in the *Archives of Dermatology*

and *Syphilology* (5: 570-578, 1922). The author's test has been modified and discussion of it amplified in numerous later papers and a book.

The precipitation method proposed in this paper is based on the employment of syphilitic serum with alcoholic extract anogens of heart muscle. In this regard it is similar to the precipitation reactions of Meinicke, Sachs and Georgi, and Dreyer and Ward.

The test proposed, however, differs from each of these reactions in essential phases.

## MASSACHUSETTS MEDICAL SOCIETY

### SECTION OF OBSTETRICS AND GYNECOLOGY\*

#### INDUCED ABORTION, FOLLOWED BY FATAL HEMORRHAGE AND SEPSIS

A thirty-nine-year-old primipara arrived in the hospital flowing profusely and evidently septic. She stated that her last period had occurred approximately four months before admission, and that an abortion had been induced. The previous medical history was irrelevant.

The patient's temperature was elevated, but the record does not state how high it was. Physical examination was negative except for an abdominal tumor mass, which rose above the symphysis and was consistent with the size of a four-months' pregnancy. One foot was protruding from the introitus. Under aseptic precautions, the fetus was extracted and the uterus curetted of retained placenta tissue. The record suggests that a large part of the placenta was lying over the internal os, and when this was removed, a tremendous amount of blood followed. The patient went into extreme shock, and was given ergot, pituitrin and stimulants. The vagina and uterus were tightly packed with gauze, and the patient was returned to bed. She died shortly thereafter.

*Comment.* It is well recognized that artificial emptying of the uterus during the second trimester is very difficult, and that hemorrhage and sepsis frequently follow an attempt to induce such evacuation. This case is said to have been self-induced; at any rate, both sepsis and hemorrhage followed. No transfusion was given, and it is doubtful whether it would have been of any value, because the hemorrhage from a uterus at this period of gestation may be perfectly tremendous. There is little in the history to criticize. It is sad.

\*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters should be addressed to Dr. Raymond S. Titus, Secretary, 330 Dartmouth Street, Boston.

that the operation lasted twenty minutes. If the bleeding had continued from the first at a startling rate, it would have been more conservative to pack the uterus and permit some of the placenta to remain, rather than to continue the operation with the idea that the uterus must be emptied. This is the cardinal treatment of any criminal abortion. In the face of very active hemorrhage, all attempts to remove the products of conception should be postponed, the immediate hemorrhage should be treated by uterine packing, and the patient should be transfused while still alive.

## DEATHS

BARNES — J. ARTHUR BARNES, M.D., of Worcester, died September 6. He was in his seventieth year.

A native of Fitchburg, Dr. Barnes received his degree from Harvard Medical School in 1900. He was a fellow of the American College of Surgeons, the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, a son, a brother and a sister.

STONE — FRANK E. STONE, M.D., of Lynn, died September 3. He was in his eightieth year.

Born in Lynn, Dr. Stone received his degree from Bowdoin Medical School in 1885. He was a member of the Massachusetts Medical Society and the American Medical Association. He was on the staffs of the Lynn and Union hospitals.

His widow, a son, two daughters and a sister survive him.

## MISCELLANY

### TUBERCULIN TESTING IN CHICAGO SCHOOLS

Findings in an extensive tuberculosis survey in Chicago schools, using the tuberculin test as a screen, are now available (*City of Chicago Municipal Tuberculosis Sanitarium Bulletin*, 18 [1938], 19 [1939] and 20 [1940]). Although it is not a new conclusion that routine skin testing in elementary-school groups is not an economical procedure, the report does contribute materially to knowledge of the epidemiology of tuberculosis and permits comparison with previous surveys in Chicago. An abstract follows:

This survey was carried out by the Chicago Municipal Sanitarium, aided by the Tuberculosis Institute of Chicago and Cook County.

The survey policy of the Municipal Tuberculosis Sanitarium had hitherto been largely oriented toward older groups. Tuberculin testing in the schools, therefore, represented a deviation from established policy and was undertaken to explore educational values, morbidity rates, and case-finding potentialities of a follow-up of the reactors and to check on existent case-finding machinery.

Since the purpose was to obtain a cross-section of tuberculosis morbidity, the survey attempted to include every Chicago school. However, it was necessary to sacrifice certain ambitions, such as a 100 per cent consent and a

thorough survey of each school. In a general way, the policy ran, "Get what consents you can in the time allotted and go on to the next school."

Kindergarten children, those in the first and eighth grades and all available students in the high schools, were examined. It was thought that a positive reaction in a kindergarten or first-grade child might have some epidemiologic significance. Eighth-grade children, on the threshold of adolescence, were included because many would not go to high school; thus it might have been the last chance to include them in a case-finding effort. In view of the many studies already made, the justifiability of high-school examination is hardly debatable.

First, the Board of Education notified the principals. Then the nurse addressed the teachers and children in each room. All were given appropriate literature, which, with the consent card, the children took home. After a proper interval, a team did the tuberculin test, and the results were read in forty-eight hours.

In all, 176,878 consents were obtained in 561 public elementary schools, 115 public high schools, 347 parochial elementary schools, 47 parochial high schools, 12 trade and vocational schools and 5 junior colleges.

A self-contained and complete mobile unit, the first known to be used in the x-ray field, was devised. On starting work the truck drove into the schoolyard and the technician selected a location as near as possible to space for extra dressing rooms. Current was obtained through a cable from a school connection.

The procedure, carefully standardized, was to give a single Mantoux test, using PPD (purified protein derivative) in an amount one tenth the usual final dose. The percentage of reactors with this dose was low compared with the experience in other urban areas, so that the dose was doubled in the latter part of the work, except with Negroes and Mexicans, who had shown marked sensitivity to tuberculin.

In the 167,345 children tested, 27,401 proved positive. To March 1, 1940, 23,532 had been x-rayed and 218 cases of reinfection-type tuberculosis had been found, of which 109, or 50 per cent, were in the moderately or far-advanced stage; in 4524 children, evidence of primary-infection-type tuberculosis was found.

The reactor rate and the primary tuberculosis rate were practically the same for boys and girls, but the incidence of reinfection-type tuberculosis was twice as high in girls. The incidence of disease among children x-rayed was higher in Negroes and Mexicans but not to the same degree as the infection rate. The Negroes had slightly less primary tuberculosis than the Whites.

The study seemed to bear out the reports of other workers who found a lack of constant correlation between tuberculin sensitivity and tuberculous calcifications.

In comparison with other metropolitan surveys, the reaction incidence in Chicago is low. This may be because no person with an open case may live in the same home with children under sixteen: contact is broken as soon as possible after discovery of the case.

Survey results confined to a district or a constellation of districts would lead to false conclusions. The survey included schools in every district and children from every economic level. The major part of the tuberculosis problem is sharply localized. About four of the seventy-five census districts account for 38 per cent of the deaths. Mortality in these areas is much higher than the general rate, namely, 196 per 100,000, as compared with 51.6 per 100,000 for the city as a whole; morbidity figures also run in the same ratio.

In Chicago, as elsewhere, decreasing mortality rates probably exerted an influence on the composition of the infection index. The rate has fallen from 147.9 per 100, 000 in 1917 to 51.6 in 1939. Over the same period, the rate has fallen from 133.9 to 34.0 for Whites and from 144.0 to 281.7 for Negroes.

In an attempt to estimate the diminution of the reactor rate, the present figures may be compared to older studies, one made by Webb of the University of Chicago in 1930-31, and the other by Novak and Kruglick of the Tuberculosis Institute of Chicago and Cook County in 1933-37. Webb tested no high school children, and Novak and Kruglick tested no elementary school children. In elementary school ages, comparing Webb's figures with the present study, since 1930-31 there has been a definite drop for each age period. Comparing high school tests for 1933-37 and 1936-39, there has also been a substantial drop for each age period, except for age twenty, only 29 students of this age were tested in the Novak study.

The specific relation between tuberculin positive reactors and tuberculosis in the home was clearly demonstrated in the present survey. The source of infection was unmistakably established in 3284 cases, but of these only 226 were new pulmonary cases.

The comparatively small number of new cases found in the families of the positive reactors was both a disappointment and a satisfaction. A larger proportion of new tuberculosis had been anticipated, but it was encouraging to know that the existent case-finding machinery is effective, since in 90 per cent of the cases the source of infection was already under supervision.

Altogether, 586 new cases of tuberculosis were found. The total cost chargeable to the survey for the 586 cases found was \$511.95 per case.

To explore its potentialities, figuratively speaking, the miniature x-ray machine was carried almost to the door step of the people in the congested areas. The equipment was hooked up to the mobile x-ray truck, and this self-contained unit, including dressing rooms, was taken to various locations.

The plan, still operative, aims at making an x-ray examination of every man, woman and child in certain areas of gross congestion, high tuberculosis mortality and low economic status.

In the school survey, lasting three years and comprising 23,532 x-ray examinations, 218 new cases were found on the first film. In the miniature x-ray survey, comprising 20,956 examinations and lasting five months, 675 new cases were found by the original x-ray film.

To summarize, during a three-year period, 167,345 children were tuberculin tested, and 23,532 x-rayed. The reactor incidence was 7.04 per cent for kindergarten and first grade, 18.82 per cent for eighth grade, 21.29 per cent for high school students and 29.97 per cent for miscellaneous schools and colleges. The rate for Negroes was twice that of Whites, and for Mexicans it was still higher.

The study showed a substantial drop in the reactor rate in Chicago as compared with older studies. The city-wide survey emphasized the fact that each district had its own reactor rate, which was allied to local mortality rates.

In 57,481 children under twelve tested with tuberculin, 9 cases of pulmonary disease were found, which is comparable with figures for this age group in the mortality tables. Facts point toward the adolescent and early adult years as the case-finding provinces. In testing adults in highly infected milieus (60 per cent reactions or more), x-ray study of the entire group is cheaper than tuberculin

testing, with x-ray examination of the positive reactors — Reprinted, in part, from *Tuberculosis Abstracts*, August, 1941

## HARVARD MEDICAL SCHOOL

Award of sixty-five Harvard Medical School scholarships totaling \$21,295, for study during the 1941-42 academic year, has been announced by Harvard University. The recipients of the scholarships are:

Chuan Wang, 1M, Hong Kong, China, Harold S. Robinson, 3M, Shantung, China, Robin G. Anderson, 2M, Passaic, New Jersey, Harold Brown, 2M, Dorchester, Massachusetts, Theodore G. Erler, Jr., 3M, Bellevue, Ohio, William J. Lahey, 3M, East Hartford, Connecticut, Sidney W. Ellery, 2M, Miami, Arizona, Elliot L. Sagall, 2M, Revere, Massachusetts, Grant V. Rodkey, 2M, Coeur d'Alene, Idaho, William Rudder, 1M, Bellingham, Washington, Thomas D. Allison, 2M, Kittanning, Pennsylvania, Robert L. Berg, 1M, Spokane, Washington, Logan O. Jones, 2M, Birmingham, Michigan.

James M. Judd, 1M, Randolph Center, Vermont, Frank E. Trobaugh, Jr., 1M, West Frankfort, Illinois, Duane H. Mitchell, 2M, Winchester, Kansas, John A. Evert, Jr., 3M, Glendive, Montana, Jesse E. Thompson, 2M, San Benito, Texas, Alvin T. Held, 4C, Columbus, Ohio, Paul A. Reinenschneider, Cleveland, Ohio, Bernard W. Robinson, Roxbury, Massachusetts, Boris P. Bushueff, 1M, Harbin, Manchou T'iao, William R. Waddell, 1M, Tucson, Arizona, James E. Kreisler, 3M, Austin, Texas, Lindley B. Reagan, 3M, Poughkeepsie, New York, David W. Williams, 2M, Washington, Connecticut.

Francis R. Lane, 1M, Somerville, Massachusetts, Richard J. Cundiff, 2M, Long Beach, California, John Q. U. Thompson, 3M, Jacksonville, Florida, Edwin W. Peterson, 1M, Denver, Colorado, David S. Speer, 2M, Bronxville, New York, James H. Strough, 3M, Canton, Ohio, Herbert R. Morgan, 3M, Bell, California, Harold F. Searles, 1M, Hancock, New York, Israel H. Schleinberg, 1M, New York, New York, Stephen L. Midey, 1M, Buffalo, New York, Harry D. L. Kaye, 3M, New York, New York, Daniel Scarra, 1M, Paterson, New Jersey, Burdick G. Clarke, 3M, Winnetka, Illinois, James P. Dixon, Jr., 1M, North Rochester, New Hampshire, Charles Averill, 3M, Methuen, Massachusetts, Theodore S. Cobbe, Jr., 1M, Canton, Ohio.

Abraham N. Barger, 2M, Greenfield, Massachusetts, Melvin B. Black, 1M, Roxbury, Massachusetts, James T. Blodgett, 3M, Woburn, Massachusetts, Frederic B. Breed, 2M, Cambridge, Massachusetts, Donald E. Brown, 2M, Beverly, Massachusetts, Robert H. Brown, 1M, Hyde Park, Massachusetts, John Burbank, 2M, Lynn, Massachusetts, Allan D. Callow, 3M, West Somerville, Massachusetts, Dante F. Campagna Pinto, 2M, Boston, Massachusetts, David Dove, 3M, South Sudbury, Massachusetts, Robert W. Gage, 3M, Needham, Massachusetts, Thomas V. Healey, 1M, Worcester, Massachusetts, Robert B. Higgins, Cambridge, Massachusetts.

Robert B. Holden, 2M, Stoneham, Massachusetts, Elmer V. Kennally, 1M, Medford, Massachusetts, Eugene F. Poutasse, 1M, Weston, Massachusetts, Cornelius J. Shea, 2M, Dorchester, Massachusetts, Robert J. Tracy, 3M, Concord, Massachusetts, Paul F. Ware, 2M, Clinton, Massachusetts, Eugene L. Watkins, 1M, Worcester, Massachusetts, Albert E. Weiner, 3M, Newton, Massachusetts, Mark S. Wellington, 1M, Amherst, Massachusetts, and Frank C. Wheelock, Jr., 2M, Springfield, Massachusetts.

## CORRESPONDENCE

## SULFANILAMIDE SPRAY

In a letter published in the November 14, 1940, issue of the *Journal*, one of us (N. C. S.) suggested the use of a sulfanilamide spray in the treatment of colds and sore throats. Its local application in infected wounds has been used with considerable success, and it seemed reasonable to think that it would have a similar effect on inflamed throats and infected nasal passages.

Three 5-gr. tablets of sulfanilamide are dissolved in an ounce (30 cc.) of hot water. The tablets go into solution better if they are finely pulverized; however, even then, a sediment remains, which is liable to clog the atomizer. Sulfathiazole goes into solution better than sulfanilamide and appears to be equally effective, although our experience with it has been limited. When one is using sulfathiazole, two 7½-gr. tablets are dissolved in an ounce (30 cc.) of hot water.

We are convinced that the effects of the spray are markedly beneficial. The majority of colds and sore throats clear up in about half the time of the usual duration. It probably has no effect on the virus that causes the cold, but is markedly effective against the secondary invaders, and the earlier the cold is treated the better chance there is of holding the latter in check.

Colds that begin with inflamed throats give the most spectacular response. In a few hours, the redness fades, and the soreness disappears. A streptococcal sore throat rarely persists over twenty-four hours.

Since January, 1941, the beginning of the winter term, we have used the spray in the treatment of colds among the students of the Putney School. The days lost because of colds in the fall, winter and spring terms, compared with those of the two preceding years, are as follows:

1938-1939 (112 pupils).	Fall term	94 days
	Winter term	104 days
	Spring term	19 days
1939-1940 (122 pupils).	Fall term	180 days
	Winter term	128 days
	Spring term..	39 days
1940-1941 (136 pupils).	Fall term	104 days
	Winter term	89 days
	Spring term	13 days

During 1940-1941, we had the best health record of any year since the founding of the school in 1934. Although we were in the midst of a severe epidemic of influenza, no serious illness occurred. There were only two cases of influenza, no cases of pneumonia, and no cases of bronchitis, which had been particularly bothersome in other years. There were a few cases of earache, but none that required paracentesis.

We do not mean to give the impression that the sulfanilamide spray was responsible for the small amount of illness, although we believe it was effective in stopping the invasion of tissues by secondary invaders, which in some cases ultimately result in sinusitis, bronchitis, pneumonia and otitis media. Furthermore, we believe it somewhat limits the contagiousness of colds.

At the Putney School, every child is inspected every day, and the slightest sign of a cold is treated immediately with the sulfanilamide spray. The treatment is continued every two or three hours for forty-eight hours, or until the cold has cleared up.

## REPORT OF MEETING

## NEW ENGLAND PATHOLOGICAL SOCIETY

A regular meeting of the New England Pathological Society was held on May 17 at the Yale University School of Medicine, New Haven. Dr. Tracy B. Mallory presided.

The first paper, on "Wernicke's Hemorrhagic Polioencephalitis," was presented by Drs. J. P. Murphy, C. O. Prickett, A. J. Waring, Jr., and H. M. Zimmerman. Employing an experimental dietary regime in which thiamin and nicotinic acid were withheld or were given in small quantities, the authors reinvestigated the problem of the etiology of Wernicke's disease, with the rat as the experimental subject. All the other vitamins were given in amounts known or estimated to be adequate for this animal. Four groups of animals were used, and in the brains of those which received no vitamin B<sub>1</sub>, or minimal amounts of it, the typical hemorrhagic and angioneurotic vascular lesions were found in the gray matter around the third and fourth ventricles and aqueduct of Sylvius. The nuclei of the vestibular nerves and of the cerebellum particularly were frequently and severely involved. The pathological findings were just as extensive when nicotinic acid was fed to the hypothiaminotic animals as when it was absent from the diet. From these studies, the investigators concluded that uncomplicated thiamin deficiency in the rat results in the production of lesions typical of Wernicke's disease; that concomitant deficiency in nicotinic acid does not significantly increase the number and extent of the lesions; that deficiency in nicotinic acid alone does not result in these changes; and that the longer the length of life of the animals not receiving B<sub>1</sub>, the severer and more extensive the polioencephalitic changes tend to become. In the discussion, Dr. M. C. Winternitz asked whether it is known how the thiamin hydrochloride deficiency produces these changes. Dr. Zimmerman answered that thiamin hydrochloride has something to do with the metabolism of carbohydrate, and it is quite possible that its effect is similar to that produced by the deprivation of glycogen and glucose. It may, of course, have something to do with oxygenation in the central nervous system, producing anoxic effects. He also noted that lesions of this kind due to vitamin B<sub>1</sub> deficiency have been seen in four species—the pigeon, rat, dog and man. Similar lesions are seen in man in the absence of alcohol, and the symptoms of those patients afflicted with Wernicke's syndrome are ameliorated by adequate amounts of thiamin hydrochloride.

The second paper, "Factors in Resistance to Tuberculosis," was presented by Drs. Bruno Gerstl and Robert Tennant. From the variance in response to the tubercle phosphate when injected into rabbits or mice (Sabin, Thomas), it was concluded that the mouse cells are able to break down rapidly the tubercle lipid, and that those of the rabbit do it at a slower pace, if at all. This ability of the mouse cells may be one of the additional factors on which the natural high resistance of the mouse to tuberculosis is based. It could be demonstrated that phosphatases alone were not able to break down the tubercle phosphate. The previous action of a second enzyme, a lipase in a general sense, was necessary. Lecithinase "A" obtained from snake venom was one of the particular lipases facilitating further splitting; it could not be ascertained, however, in the parenchymatous organs of the mouse. Another lipid-splitting enzyme was obtained from the mouse liver and differentiated from other esterases by using quinine as an inhibitor. Its action, com-

bined with that of phosphatases, effected 80 to 90 per cent splitting of tubercle phosphatide or lecithin, whereas either enzyme alone accomplished little. Comparison of the reaction velocities of phosphatases of the three species, mouse, rabbit and guinea pig, showed marked differences. When the tubercle phosphatide was used as substrate, the mouse enzymes produced a rapidly progressing cleavage, the guinea pig lung, none at all, the effect of the rabbit organs was in between. Experiments in progress suggest that this difference is due not only to variations in enzyme concentrations but also to the inhibition exerted by the tuberculostearic acid split off from the phosphatide. This inhibition varies with the species from which the enzymes are derived. The discussion was opened by Dr. Valy Menkin, who stated that, a number of years ago (1928, 1929), Lurie, of the Henry Phipps Institute, demonstrated that rabbits infected with tubercle bacilli displayed differential destructive capacity in various organs. The bacilli were rapidly disposed of by the spleen, liver and bone marrow while, on the other hand, these micro-organisms persisted in the lungs and kidneys. There has been no adequate explanation offered for this difference in local organ immunity. Dr. Menkin wondered whether the findings of Dr. Gerstl on the splitting and liberation of phosphorus compounds could not yield a clue to this fundamental problem. In other words, is it possible that these same organs would yield differences in chemical activity that could in turn be correlated with the number of recoverable bacilli in the respective organs? He considered this to be of definite interest, since the speaker's thesis was apparently designed to show that some of the factors of resistance in tuberculosis are to some extent associated with the ability of tissues to split phosphatide compounds. He was not certain whether or not the last chart shown suggested the possible existence of any such quantitative correlation in the organs studied. Dr. Gerstl replied that Corper, in 1931, also demonstrated that canine lungs, liver and spleen are able to destroy tubercle bacilli when incubated for several weeks. The charts shown indicated that there is a difference in the rate of splitting the tubercle phosphatide when organ extracts of the same species—and, still more, when organ extracts of the mouse, rabbit and guinea pig—are compared. This ultimately results in a quantitative difference. These investigations differ from those first mentioned by the employment of purified extracts and by the attempt to determine the enzymes responsible for the breakdown of the tubercle phosphatide.

The third paper, "Experimental Brain Tumors Produced with Benzpyrene," was presented by Drs. H. Arnold and H. M. Zimmerman. Attempts at producing cerebral neoplasms with benzpyrene have in the past yielded uniformly negative results. In most of these experiments, the carcinogen was administered in an oily vehicle such as lard, cholesterol and lanolin, and only granulomatous reactions were produced at the sites of benzpyrene implantation. In the present experiment, 51 mice of the C-3H strain had pellets of the pure carcinogen implanted in the right cerebral hemisphere. Up to the three hundred and twenty-fourth day of the experiment, 27 of the animals died or were killed, and of these, 22 had intracranial neoplasms. Eleven were gliomas, 10 were sarcomas, and 1 was a mixed tumor of gliogenous and sarcomatous origin. Included among the gliomas were 3 glioblastomas multiforme, 1 oligodendroglioma, 1 astrocytoma, 3 ependymoblastomas, 1 medulloblastoma and 3 unclassifiable gliomas. Most of the tumors have been transplanted successfully in the subcutaneous tissues of other mice of the same strain. It has been found that the tumor transplants are of great value in the classification

of the experimental neoplasms because typical morphologic features, absent in the original tumors, frequently appear in the second and third hosts. In the discussion, Dr. Zimmerman stated that it is interesting to speculate on the reasons why previous benzpyrene experiments to produce intracranial neoplasms were unsuccessful. Perhaps the wrong animal was used, or, more probably, the carcinogen was inserted in the wrong vehicle. It is quite possible that the granulomatous change that may have been produced was too great, and killed the animal before the tumor developed. It is also interesting to speculate on how the carcinogen acts. Is it merely a catalyst? Since gliomas practically never metastasize outside the brain, it was believed that there must be some antagonism to the growth of ectodermal gliomas on the part of mesodermal tissue. The fact that these tumors have been successfully transplanted in subcutaneous tissue proves that there is no local antagonism. Dr. Mallory mentioned that he had seen a malignant teratoma of the ovary containing glial tissue, with omental implants of the glial tissue, and asked whether any of the mixed tumors had appeared in the transplant as mixed tumors. Dr. Zimmerman answered that it is possible to get mixed tumors in the transplant. On the other hand, transplantation of the mixed tumors is one method of separating them. One of the transplants may yield a glioma, and the other a sarcoma, a process quite analogous to the isolation of bacteriologic colonies.

The next four papers dealt with kidney and cardiovascular disease. The general survey of the experimental approach was presented by Dr. M. C. Winternitz. The results of bilateral nephrectomy in the dog have been found to contrast sharply in various ways with those following ligation of both main renal arteries. This has been pointed out for the blood pressure, which does not usually rise and never attains significant proportions after ablation of both kidneys, but which, as a rule, does become elevated after ligation of both renal arteries. Other contrasts, thus far not emphasized, involve survival time, rate of rise of blood nonprotein nitrogen, quantitative change of electrolytes of the blood with associated effects on cardiac function and, finally, the ultimate contrasting morphologic processes manifested after the two procedures. Moreover, the bilaterally nephrectomized animals have proved valuable for determination of the acute functional and structural effects caused by the injection of whole extracts and also of fractions of extracts of kidney and other organs of homologous and heterologous species. The results of these experiments have encouraged the utilization of similar extracts with normal dogs, and chronic counterparts of the acute processes are now being obtained. Dogs survive bilateral nephrectomy as long as ten days, the average is seven, and very few die before the end of the fifth day. The blood pressure shows little change. Vomiting occurs almost invariably. At autopsy, no specific gross lesions are encountered. Occasional sub-endothelial, valvular and visceral hemorrhages, as well as focal necroses involving heart muscle and smooth muscle of artery wall, alimentary or genitourinary canal, are rare but important findings. Ligation of the main renal artery of both kidneys may result in a moderate but definite rise in the blood pressure, which tends to fall again on the last day of survival of the animal. The nonprotein nitrogen of the blood rises rapidly, and by the third postoperative day equals that of the sixth day after bilateral nephrectomy. Vomiting is a prominent feature of the short clinical course. The animals give evidence of serious illness rather suddenly during the latter part of the second postoperative day and then become progressively ill, with signs of central nervous-system irritation, includ-

ing nystagmus and, rarely, convulsions. The short survival period contrasts sharply with that of the nephrectomized animal. Death has occurred after ligation of both renal arteries not later than the fourth postoperative day, whereas animals whose kidneys have been removed often live twice, rarely three times, as long. The gross post-mortem examination shows hemorrhagic lesions of wide distribution similar to those described as following much longer periods of hypertension and azotemia after constriction of the renal arteries. Edema, hemorrhage and necrosis of muscle, including heart muscle, smooth muscle of blood-vessel walls, hollow viscera and diaphragmatic muscle, are the lesions encountered. It should be emphasized that a minimal representation of the extensive anatomic changes found after ligation of both main renal arteries may be demonstrated by detailed examination when death follows removal of the kidneys. Consequently, absorption from the necrotic kidneys cannot be considered the only responsible factor. After ligation of both ureters, the lesions encountered, except for those of the kidney, conform to those that result after ligation of both main renal arteries. The results of the injection of extracts of necrotic and of normal dog kidneys into the bilaterally nephrectomized dog are strikingly similar. The injection may be associated with a slow rise in blood pressure, which reaches a maximum only after several minutes and then falls very gradually over an even longer period before it drops to the preinjection level. Nystagmus, vomiting and occasional convulsions may occur, with or without fall in pressure. The blood nonprotein nitrogen of the injected animal has a tendency to rise abruptly, as that of the ligated animal does. This rise is not due to the nitrogen content of the injected protein. The anatomic changes duplicate those that follow ligation of both main renal arteries. Their extent is associated both with the survival time of the animal and with the amount of extract received. Crude extract of pig kidney, obtained by the Buchner press or the Latapie technique and injected into nephrectomized dogs, has the same effects as dog kidney extract. The depressor effect is more constant than with dog kidney preparations. Dialyzation does not deprive the extract of either its vasopressor or its dilator properties. Intravenous injection of tissue extracts, as is well known, exerts a profound effect on blood coagulation time and actual clot production. It should be emphasized that many of these effects are encountered after partial or complete renal arterial or ureteral occlusion and that they include both vasal depressor and pressor actions, changes in blood nonprotein nitrogen, and electrolytes, hemorrhage and necrosis of muscle, including both heart muscle and the smooth muscle of blood vessel walls, and hollow viscera particularly. These occur in various combinations, and the fact that at least some may be eliminated by particular treatments indicates their separate origin.

One aspect of this problem, "Electrolytes, Potassium in Particular, and Cardiovascular Renal Disease," was presented by Dr. S. H. Durlacher. The electrocardiographic findings in potassium poisoning are similar to those seen in experimental renal insufficiency produced in animals receiving a normal diet. The serum potassium reaches lethal levels following extirpation of the kidneys and bilateral ligation of the renal arteries or ureters. The survival time of rats fed a diet deficient in potassium with consequent diminution of muscle and serum potassium, is significantly increased following the above procedures over animals fed a control diet. The animals die after a prolonged period, with markedly elevated blood non-protein nitrogen. The serum potassium levels are not within the fatal range at the time of death. Hypertrophy

of the rat kidney, which occurs after a three-week period on a low potassium regime, consists in dilatation of the tubules of the medulla and pyramid, with hyperplasia of the lining epithelium.

Another aspect of the subject, "Tissue Extracts, Blood Coagulation and Associated Anatomical Changes," was presented by Dr. R. Katzenstein. The well-known effects of tissue extracts on the clotting time of the blood and the production of thrombi are related to their content of thromboplastic substance. This varies considerably with different tissues. Lesions of the wall of heart and blood vessels are not necessary for thrombosis. Moreover, such mural changes occur without superimposed thrombi if the stability of the blood from the standpoint of its coagulation is not advantageous. Location of thrombi after injection of tissue extracts indicates variation in the coagulation time of the blood in different parts of the vascular bed and suggests that different organs participate in effecting the balance of the coagulation time.

Finally, the "Contributions to Cardiovascular Renal Disease from the Biochemical Approach" was presented by Dr. E. Mylon. Renin, the pressor substance present in normal renal tissue, was shown either to be attached to or to be a small molecular protein that is not precipitated by centrifugation at speeds of 50,000 revolutions per minute. Purification of the material diminishes the angioneurotic activity, although a blood pressure rise of 30 mm. of mercury is produced when quantities equivalent to 1 gamma of nitrogen per kilo are administered. This pure product is free of all enzymatic action, in contrast to the less-refined "renin-C" of Page and his co-workers. The necessity of an intermediary product such as "angiotonin," produced by Page, is questioned in the light of previous experiments by Landis, Montgomery and Speckman, who showed that the pressor substance acted only in the presence of an intact sympathetic nervous system. The failure of renin to produce contraction of an isolated artery is therefore not surprising. The depressor activity of crude kidney extracts, as well as similar preparations of other organs, is related to the thromboplastic activity of these products. When clot formation is inhibited by heparinization or by the postinjection negative phase of blood clotting, only a slight fall in blood pressure occurs. Kidney extracts do not, therefore, possess a strong depressor substance, and the sharp and sustained fall in pressure observed following the injection of these materials is dependent on their thromboplastic action. In the discussion, Dr. Menkin referred to his observations made recently on some preliminary studies on the subject of shock. This was induced by utilizing the method described by Dr. Walter B. Cannon a number of years ago, which, in brief, consists in studying blood-pressure changes after severe injury induced in the thighs of cats by crushing the muscles. The blood pressure is measured by the usual technique of introducing into the carotid vessel a cannula connected to a mercury manometer. In his experience, almost immediately after the severe injury has been induced, there is a sharp drop in blood pressure, which is sustained throughout the period of the acute experiment. This may last one or two hours. Furthermore, it is of interest that in these animals the rate of blood coagulation seems to be hastened, as evidenced by the frequent necessity of washing clots from the carotid cannula, a state of affairs not observed in animals with uninjured tissues. In view of the very interesting observations of extracts of tissues favoring the formation of thrombi, Dr. Menkin wondered whether thromboplastic substances may not be constantly diffusing into the circulation from an area of extremely

## IS THERE A COMMON DENOMINATOR IN SCLERODERMA, DERMATOMYOSITIS, DISSEMINATED LUPUS ERYTHEMATOSUS, THE LIBMAN-SACKS SYNDROME AND POLYARTERITIS NODOSA?\*

BENJAMIN M. BANKS, MD†

BOSTON

**S**CLERODERMA, dermatomyositis, disseminated lupus erythematosus, the Libman-Sacks syndrome and polyarteritis nodosa constitute a group of diseases of unknown etiology that are apparently unrelated in their presenting clinical features. The widespread visceral involvement in each is obscured by certain dominating focal manifestations, which serve as the clinical basis for the differentiation of these syndromes from each other. Striking similarities, however, in the detailed pathology of these various conditions require evaluation for a possible relation or common denominator among them. This communication reports a case of scleroderma that presented visceral features common to other diseases in this group. The systemic symptoms and pathology of these syndromes are discussed to define their differences and to determine whether any common relation exists.

### CASE REPORT

A 51 year-old unmarried secretary was first admitted to the hospital for study on August 23, 1939, because of generalized pigmentation suggestive of Addison's disease. The present illness first became manifest in the fall of 1937, when she noted that on awaking in the morning there was marked numbness and coldness of both hands, especially the right. In the winter of 1937-1938, both hands on exposure to cold became painful and showed whitish blue discoloration. There was never any pain or numbness of the feet. In January 1938, a diagnosis of arthritis was made, and x-ray films of the hands were interpreted as showing arthritic changes. The patient lost 18 pounds on a reducing diet, and received two series of vaccine injections, each lasting approximately 3 months. She consulted another physician in the spring of 1939 because of persistent severe pain in the right hand hardness of the finger tips bilaterally and difficulty in typing. He doubted the diagnosis of arthritis, and believed that the patient had scleroderma. Because of a basal metabolic rate of -27 per cent, the patient was given

between 2 and 3 gr. of thyroid daily which she took regularly to the date of admission. She also received Brewer's yeast, belladonna and phenobarbital. Her finger tips became much softer, and she could type without difficulty. During the summer of 1939, her right wrist became very stiff and painful, and the fingers gradually contracted and became so stiff that she could not close her fist tightly. The patient had noticed that her skin darkened rapidly every summer but that throughout the last year her chest had remained tanned. During that winter the skin continued to darken and became very shiny. Her appetite and strength remained fairly good, and her weight before admission was 128 pounds. Two weeks before admission, she developed a slightly sore area at the base of the 5th metatarsal bone of the left foot, which a week later became infected and discharged pus.

The past history was not remarkable. The patient had always been in excellent health. She had typhoid fever 27 years before admission and a hysterectomy for fibroid uterus 19 years later. There was no history of scarlet fever or rheumatic fever. The system and family histories were noncontributory. She had used no tobacco or alcohol.

Physical examination revealed intensely tanned skin, the backs of the hands being almost negroid in appearance. The skin of the anterior chest was glistening brown and stretched very tightly over the underlying structures. The skin over the malar portion of the face was likewise very taut. On the backs of the hands palms and fingers, the skin and subcutaneous tissues were thick and brawny. In the mouth there appeared one small area that was suggestive of pigmentation. Hyperkeratotic plaques were abundant on the abdomen. The fundi and the thyroid gland were normal. The heart and lungs showed no abnormalities, the blood pressure was 114/74. Abdominal examination revealed no unusual findings, and the peripheral reflexes were equal and hyperactive. The fingers were tapering and cold, and neither hand could close completely. The right wrist was extremely painful to palpation and movement. The skin over the legs was normal in texture except for moderate brawny edema of the left leg, with slight pitting at the ankle. At the base of the 5th metatarsal on the left, there was a fairly well healed infection. The dorsalis-pedis pulsation was bilaterally palpable.

The laboratory data, in view of the subsequent course, were of considerable interest. Of two routine urine analyses, the highest specific gravity was 1.003, and the sediment on one occasion showed 2 red blood cells in thirty fields. The red-cell count was 3,930,000, with a hemo-

†Internist in Medicine, Harvard Medical School and Associate Physician, Beith Israel Hospital.

globin of 11.6 gm. (80 per cent Sahli), and the white-cell count was 12,200, with 73 per cent polymorphonuclear cells (10 per cent band forms) and no eosinophilia. Blood chemical findings included a nonprotein nitrogen of 27 mg., a urea nitrogen of 11 mg., a sugar of 99 mg. and a cholesterol of 195 mg. per 100 cc. Total protein on admission was 7.1 gm., with albumin 3.7 gm. and globulin 3.4 gm. The blood-sodium level was 321 mg., and the chloride 295 mg. per 100 cc. The serologic findings were negative.

During the hospital stay of 7 days, the patient's oral temperature reached an average of 99.4°F. daily, with a pulse rate usually of 90, and respirations of 20. A diet with a calculated salt intake of 5 gm. daily was ordered, and an actual intake of 3.2 gm. was maintained after the 1st hospital day. During the first 4 days the fluid intake was high, and there was a diuresis averaging more than 3500 cc. daily, the total urinary chloride exceeding 4.65 gm. Thereafter, fluid intake and output fell to normal levels, and the total urinary chloride was 1.40 gm. The 24-hour urinary creatine varied from 89 to 35 mg., and the creatinine from 1013 to 486 mg. The blood pressure, taken at frequent intervals, showed a gradual decline, reading 95/60 on discharge. The wrist was treated with hot, Epsom salt soaks, and the subsiding infection of the foot with hot, boric acid compresses and elevation. Both regions improved rapidly. It was considered that the blood-pressure readings, the levels of sodium and chloride in the blood, and the normal 24-hour urinary chloride excretion on a diet fairly low in salt were sufficiently significant to eliminate the diagnosis of Addison's disease.

The patient experienced pain and constant edema in the ankles during the next 3 months. She developed numbness in the left side of the face and about her mouth, aggravated by cold. The mouth itself felt puckered, and the tongue tingled, without any relief after taking nicotinic acid. For 3 weeks before the second admission to the hospital, the swelling of the ankles had increased considerably, and the patient developed dyspnea and orthopnea, with a loose croupy cough.

The patient was admitted for the second time on November 22, 1939, when she appeared very ill, dyspneic and orthopneic, with pale and slightly cyanotic lips. The scleroderma and pigmentation were unchanged. The fundi were normal. There were signs of fluid in the chest on both sides posteriorly below the 7th interspace, extending well forward into the axillas. The apex impulse of the heart was palpable at the left anterior axillary line in the 5th interspace, and there was slight enlargement to the right. By percussion, no increase in supracardiac dullness was apparent. The heart action was regular and rapid, and the rate was 110, with sounds of fair quality; there were no murmurs. The pulmonic second sound was louder than the aortic second, and the blood pressure was 148/102. The abdomen was not remarkable except for tenseness suggestive of ascites. Neither the liver nor the spleen could be felt. There was marked edema of the lower extremities to the mid-thigh, and moderate pitting edema of the sacrum.

Laboratory studies showed a urine concentration varying from 1.010 to 1.020, with a very slight trace to trace of albumin, the sediment containing a few white cells, rare red cells, 2 to 4 granular casts and 1 or 2 hyaline casts per high-power field. The red-cell count was 3,720,000, with a hemoglobin of 10.2 gm. (70 per cent Sahli), and the white-cell count was approximately 18,000, with 87 per cent polymorphonuclears. A stool examination was negative for occult blood. The blood nonprotein nitrogen

was 42 mg. per 100 cc. on admission, and 62 mg. 2 days later. The blood cholesterol was 255 mg. per 100 cc., the sugar 120 mg., the carbon dioxide combining power 55 vol. per cent, the total protein 6.0 gm., the albumin 3.3 gm., and the globulin 2.7 gm. per 100 cc. The blood-chloride level was 440 mg. per 100 cc. X-ray study revealed enlargement of the heart, chiefly to the left, with diffuse haziness of the lung fields and mottling at the bases interpreted as showing congestive changes. The electrocardiogram revealed normal rhythm, a rate of 110, left-axis deviation, notched and widened QRS complexes, probable intraventricular block, deep S<sub>2</sub>, diphasic T<sub>1</sub>, elevated ST<sub>3</sub> and ST<sub>4</sub>, and a PR interval of 0.2 second.

On admission, the temperature was 100°F. by mouth, and rose to 101° before exitus. The pulse averaged 110 to 120, and the respirations 20. The patient was seen by a consultant, who wrote, "I believe that this woman is suffering from a diffuse arterial pathologic process that falls into the lupus erythematosus group." Treatment included high-vitamin diet, restriction of fluids, digitalis, and thiamin chloride intramuscularly and intravenously. On the night of the 2nd hospital day, the patient experienced an attack of pulmonary edema, which responded to morphine, atropine, tourniquets, venesection and oxygen by Boothby mask. On the following day, 750 cc. of thin amber fluid was removed from the right pleural cavity. The circulation time by the calcium gluconate method was 19 and 22 seconds. No diuresis resulted from the intravenous injection of 1 cc. of Mercupurin, nor from the similar administration of hypertonic glucose solution. The patient became semicomatose, developed marked difficulty in getting air in and out of the lungs, had convulsive twitchings, and died on the 5th hospital day.

*Autopsy:* The body showed good development and fair nourishment. Marked pitting edema was present in both lower extremities, extending almost to the crests of the iliums. In the exposed portions of the body, the skin was taut, inelastic and a shiny tan brown. This brownish pigmentation was most marked on the face and neck and over a collarlike area on the upper thorax. On the under surface of the tongue the mucous membrane had an irregular brownish pigmentation, and both buccal mucosae had small minute spots of brownish pigment. No lymphadenopathy was found. The fingers bilaterally revealed a peculiar firm nodularity of the terminal phalanges, not quite typical of clubbing. The skin in these areas was taut, tense and hard. No evidence of muscular atrophy was noted in either the upper or the lower extremities. On section, the musculature was of firm consistence and dark red brown.

There was 200 cc. of clear, straw-colored fluid in the peritoneal cavity, a total of 700 cc. in both pleural cavities, and 300 cc. in the pericardial sac.

The heart weighed 285 gm. and was increased in size, with moderate dilatation of the right side and definite hypertrophy of the left ventricle. The myocardium everywhere was of firm consistence. The valves and mural endocardium were normal. After injection and dissection, the coronary vascular tree appeared to be patent throughout both sides of the heart. The left ventricle measured 1.6 cm. in thickness, the right ventricle 0.5 cm.

The lungs, except for a small portion of each upper lobe, were solid and firm in consistence, with no palpable crepitation.

The spleen, which was of rather firm consistence, weighed 145 gm.

The liver weighed 1540 gm. and appeared normal except for slight congestion about the central areas.

Each kidney weighed 145 gm. The fibrous capsules

were thin, and stripped easily. The outer surfaces were smooth red gray, a slight fine granularity being visible and palpable. The cut surfaces were markedly congested, and the blood vessels stood out quite prominently in the cortex and the medulla, which were sharply demarcated. The cortex measured approximately 0.8 cm. in width, it was of uniform appearance, and the glomeruli were seen as minute pin points. No degeneration in the tubular regions was noted.

Both adrenal glands were of normal size and shape, with normal appearance on section. The remainder of the organs, including the thyroid and parathyroid glands and the brain, were not remarkable.

Cultures of the heart's blood and the pericardial fluid were sterile.

At microscopic examination, sections of the heart revealed extensive diffuse fibrosis throughout, especially marked on the right side. In some parts of the right ventricle most of the heart wall consisted of a condensed stroma and old avascular fibrous tissue, with scattered, small, slightly sclerotic blood vessels traversing the sheet of dense fibrous tissue. No acute arterial lesions were present in any of the sections, and there were no changes

subacute necrotizing arteriolitis (Fig. 1). The glomeruli were not decreased in number, but were swollen and increased in size, the swelling being especially marked in the basement membranes about the capillary loops in the tufts, which were widened and had a hyaline appearance. The afferent arterioles likewise were more prominent, owing to swelling of their basement membranes, but there was no chronic hyalinizing arteriolar sclerosis. The acute necrotizing inflammatory process chiefly involved a medium sized artery about the size of an interlobular artery. This reaction could be seen to spread into the afferent arterioles and then up into the capillaries of the glomeruli. The intimal coat was swollen and revealed

FIGURE 1. *Acute Necrotizing Arteriolitis and a Glomerulus with a Thickened Basement Membrane.*

suggestive of old healed arterial lesions, although the walls of the small arteries and arterioles revealed slight edematous thickening of their muscular coats. The valves were normal.

In the lungs, there was a diffuse pneumonic process, showing all stages of consolidation. Throughout the pulmonary tissues, the smaller blood vessels showed slight thickening, with edema of the medial muscular coats. In some places, one could note a ring of vacuoles, which appeared to separate the intimal coat from the media. Various sections revealed some fibrosis throughout the pulmonary tissue.

The arterioles around the adrenal capsule showed a slight but definite sclerosis of their walls. The parenchyma and cortex, however, were normal.

All sections of the kidneys revealed a diffuse acute and

FIGURE 2. *Three Stages of Arteriolitis.*

*The arteriole on the extreme left is similar to that in Figure 1. Note the thickened wall and the cellular proliferation in the arteriole of the extreme right.*

marked proliferation of its cells, with marked narrowing of the lumen of the vessel. In many areas the walls of the arteries were edematous and necrotic, and were the site of deposits of purple-staining crescents of fibrin, with scatterings of polymorphonuclear cells. Several sites of rupture of the necrotic muscular medial coat of the artery, with exudation of polymorphonuclear cells into the surrounding stroma, were found. In other areas, this acute process appeared to be in the stage of healing, with lymphocytes predominating in the inflammatory infiltration and fibroblasts obliterating the vessel lumen. There was evidence of a completely healed stage, with small canalizing lumens that traversed the occluding mass of fibrous tissue within the former lumens of the vessels (Fig. 2). The tubules, as a whole, were slightly dilated, and their epithelial cells swollen and granular. There was only one wedge-shaped area of acute necrosis.

The parathyroid and thyroid glands were normal in all sections.

Sections of skeletal and diaphragmatic muscle presented no abnormalities of cells, stroma or blood vessels.

The epidermis revealed no atrophy, but the basal cells contained an increased amount of pigment. The dermis itself was slightly thickened. Scattered, otherwise normal, capillaries had a collar of lymphocytes about them. No degenerative changes in the collagen or elastic fibres could be seen.

The remainder of the sections, including those of the brain and cord, showed nothing worthy of remark.

The anatomic diagnoses were: acute and subacute necrotizing arteritis of kidneys, diffuse fibrosis of myocar-

dium; pigmentation of skin; chronic passive congestion of lungs and spleen; and confluent bronchopneumonia.

In many of its features, this case illustrates the classic characteristics of scleroderma. The history of Raynaud's disease, the sclerodactylia, the symptoms of arthritis with x-ray confirmation, and the temporary improvement with thyroid medication are typical. The sensitivity to sunlight, however, as manifested by deep and persistent bronzing of the exposed surfaces, was unusual, and reminiscent of the even more striking sensitivity noted in dermatomyositis and systemic lupus erythematosus. So intense was the pigmentation that the first hospital admission was for the express purpose of evaluating the possible presence of Addison's disease. A similar situation prevailed in the case reported by Talbott and his colleagues.<sup>1</sup> It is significant that throughout the first hospital stay the patient's temperature reached 99.4°F. daily and the pulse 90 while the patient was resting in bed, even after the minor local infection in the foot had completely subsided. This was definite evidence of a systemic reaction not usually seen in scleroderma. Evidence of renal involvement at this time was lacking; the urine analysis was negative, the nonprotein nitrogen of the blood was within normal limits, and the blood pressure was not elevated. Excretion of creatine, as often noted in scleroderma and dermatomyositis, was increased. At the time of the second hospital admission, three months later, failure of both the right and left sides of the heart was evident, and there were the albuminuria, microscopic hematuria and casts, and terminal azotemia seen in systemic lupus erythematosus and polyarteritis nodosa.

At post-mortem examination the extensive myocardial fibrosis, with adequate coronary circulation, and the pulmonary fibrosis were arresting findings, and recalled the marked increase in the connective tissue of the viscera reported by Matsui<sup>2</sup> in his cases of scleroderma. The striated muscle was normal. Neither the adrenal nor the parathyroid glands showed pathologic lesions. The kidneys in gross seemed essentially normal except for congestion, but microscopically they revealed widespread acute and subacute arteriolitis such as one would expect to find in a fulminating case of systemic lupus erythematosus. In this patient, the two basic pathologic changes of scleroderma—proliferation of connective tissue and alterations in the arterioles—were manifested in various internal organs. A case of diffuse scleroderma with identical changes in the renal arterioles, but without the visceral fibrosis, was reported by Masugi and Yä.<sup>3</sup>

## SCLERODERMA

Credit has been given to Curzio, of Naples, for the first description of an authentic case of scleroderma in 1752.<sup>4</sup> The condition occurs most frequently in the fourth and fifth decades, although people of all ages may be affected. The female sex predominates at least in the ratio of 2:1. The onset may be slow,—with prodromal symptoms of malaise, joint pains, asthenia and loss of weight,—or rather sudden, following a systemic infectious disease such as influenza. Other cases appear insidiously after a long history of Raynaud's disease. A smaller number of cases have followed acute arsenism. Two forms are recognized. The circumscribed type may consist of small patches of thickened skin, often about the neck (morphea), linear streaks along the course of nerves or blood vessels and sclerodactylia involving the fingers, usually in association with Raynaud's phenomenon. The diffuse form may arise from the circumscribed, or may appear first as a widespread involvement. Progressing with variable speed through the three stages of edema, induration and atrophy, the affected areas become brawny and hidebound. Pigmentation is common, from an ivory or yellowish tint to a deep bronze, especially over the exposed portions of the body, where it is indistinguishable from Addisonian coloring. Cutaneous sensation and both deep and superficial reflexes are usually well preserved. In half the generalized cases, the pain, swelling and stiffness of the joints simulate a severe and extensive arthritis. Atrophy of voluntary muscles, with contractures about the joints, serves further to limit motion. Involvement of the muscles of the tongue, soft palate and larynx is not uncommon. In one third of the cases, vasomotor disturbances are prominent. Calcification in the skin, often in the form of nodules, has been repeatedly noted. The eye grounds are normal. Aside from the progressive weakness and loss of weight, there are usually no constitutional symptoms until late in the disease. There is no fever, or any characteristic change in the blood other than a mild anemia. The basal metabolic rate is normal, and the blood calcium and phosphorus levels are usually not significantly altered. X-ray films of the hands are usually interpreted as showing osteoporosis and arthritic changes. Urinary excretion of creatine is definitely increased.<sup>5</sup> The course may be measured in weeks or years, and remissions are not unusual.

The pathology, extensively studied by Matsui,<sup>2</sup> is not limited to the skin, but affects all the viscera of the body, although one or more of the organs show a predominance of findings. The two

characteristic processes are proliferation of the connective-tissue stroma and changes in the small arterioles. The thickening of the connective tissue leads to rupture and disappearance of elastic fibers. In the blood vessels, there may be hypertrophy of the smooth muscle of the media, with infiltration of connective-tissue fibers, a thickening of the intima, with narrowing of the lumen, or complete obliteration, with thrombus formation. The changes in the skin and subcutaneous tissues exemplify both these processes. The epidermis is only slightly altered, whereas the corium shows hypertrophy of collagenous tissue, with obliteration of the papillas and replacement of fatty tissue, compression and atrophy of the sweat glands and hair follicles, and an obliterative endarteritis, with thickening of the media and adventitia and perivascular lymphocytic infiltration. There is atrophy, with similar changes in the voluntary muscles, subjacent or farther removed, and some general osteoporosis more marked in the affected regions, especially the terminal phalanges. The bone marrow becomes aplastic. Fibrosis of the lungs may occur and may result in pulmonary hypertension and dilatation of the right side of the heart. The kidneys often show changes in the blood vessels, with or without sclerosis of the glomeruli, tubular degeneration and general fibrosis. One or more of the endocrine glands commonly manifest atrophic or sclerotic changes.

Studies on the etiology of scleroderma have followed four main channels: endocrine dysfunction, vascular changes, disorders of the nervous system, and miscellaneous toxic and infectious agents.

The finding at autopsy of alterations in one or another of the endocrine glands, especially the pituitary and the thyroid gland, and the clinical evidence of glandular imbalance, occurring concomitantly in cases of scleroderma, have tended to implicate the glands of internal secretion. Matsui,<sup>2</sup> noting a diminution in the chromogenic cells of the pituitary gland, stressed its role in the pathogenesis. Others,<sup>6</sup> because of the Addisonian pigmentation and myasthenia, have suspected the adrenal glands. Most observers,<sup>7-9</sup> however, have considered the changes in function and histology of the endocrines to be secondary manifestations of the disease. They point out that scleroderma occurs with both hyperthyroidism and hypothyroidism, and consider that the beneficial effects that sometimes follow the use of thyroid medication are due to its local effect on the circulation of the skin and its general effect on metabolic processes. On the other hand, Leriche and Jung<sup>10</sup> maintain that scleroderma is a cutane-

ous form of chronic hyperparathyroidism, and advance considerable laboratory and clinical evidence in support of their views. In young pigs and rats, the injection of parathyroid extract has reproduced the disease. The calcium content of the skin in scleroderma is greatly increased, whereas the bones show osteoporosis. Surgical removal of the parathyroid glands in patients with scleroderma has resulted, according to Leriche and his associates,<sup>11</sup> in considerable improvement in most cases, and microscopic examination of the resected tissue usually shows hyperplasia. Leriche summarizes his opinion in the statement that the parathyroid glands are the primary, the bones are the intermediate, and the skin is the final site of the disturbance. Nevertheless, the data from metabolic studies are somewhat at variance with this concept. In hyperparathyroidism, the blood phosphorus content is low, the calcium is usually elevated, and urinary excretion of calcium is increased. In scleroderma, the blood levels of phosphorus and calcium are usually normal, and a negative calcium balance is lacking. The calcinosis of tissues may be due to local causes rather than to general hyperparathyroidism, and the osteoporosis is often confined to the affected regions.

The evidence that vascular changes play an important role in the causation of scleroderma is plentiful and impressive. Locally, the common association with Raynaud's disease, and the histologic demonstration of endarteritis and perivascular round-cell infiltration are classic features recognized by all investigators.<sup>2-4, 7, 9, 10, 12, 13</sup> Stokes<sup>3</sup> has considered that the basic disturbance is an endarteritis, the huge increase in connective tissue being essentially a fibrosis such as follows reduction in blood supply. That this lesion of blood vessels is fundamental and widespread, and not confined merely to the skin and underlying tissues, is indicated by the autopsy reports published by numerous observers.<sup>2, 11-16</sup> Marinescu and his co-workers<sup>14</sup> reported 5 cases of scleroderma, one of which at autopsy showed extensive arteriolar changes in the skin, heart, kidneys, nervous system and other organs. Matsui<sup>2</sup> described a case, with marked arteriolar changes in the kidneys and, to a lesser degree, in various other organs. The case reported in this paper offers further evidence along these lines.

The high incidence<sup>12</sup> of Raynaud's phenomenon in scleroderma has drawn attention to the part that the sympathetic nervous system plays in the disease. Brown and his associates<sup>17</sup> have investigated the factors of vasospasm and local disturb-

ances in the capillary bed. They found a sharp diminution in the number of open capillaries per unit area of skin, with the blood flow easily disturbed or slowed to a stop by lowering the temperature several degrees. The capillary loops were large, distorted and irregular, with outlines frayed and indistinct. They believed that although changes in vasomotor tone were important in scleroderma, they were not the primary cause. Clinically, the effects of sympathectomy and of Mecholyl iontophoresis have in some cases been beneficial. Sympathectomy has resulted in improvement in some cases not previously benefited by removal of the parathyroid glands, and the reverse has also been true. Lewis and Landis,<sup>18</sup> however, on the basis of considerable experimental study, believe that the role of the sympathetic nervous system is much less significant than purely local functional and structural changes in the digital arterioles in the circumscribed form involving the fingers.

Data concerning the relation of infectious and toxic agents to the pathogenesis of scleroderma are almost entirely clinical. The onset after erysipelas, hepatic infections and rheumatic states has led to the theory that the disease is a sequel of many infectious diseases. The appearance of scleroderma after acute arsenism or plumbism and the reports of increased amounts of arsenic or lead in the skin in some of these cases have inclined some observers to raise the question of a toxic origin of the condition.

#### DERMATOMYOSITIS

First described in 1887, independently by Hepp,<sup>19</sup> by Wagner<sup>20</sup> and by Unverricht,<sup>21</sup> who gave it its name, dermatomyositis presents a clinical syndrome that may vary widely. Most commonly it affects people of middle age, with children next in frequency, but cases at all ages and in both sexes have been described. There is usually an insidious onset, with prodromal symptoms for several weeks consisting of weakness, general malaise, anorexia or vomiting. The diagnostic triad of edema, dermatitis and myasthenia then appears, each varying in degree from case to case. In one fourth of the patients there is erythema and edema of the eyelids and face. The skin rash may be widespread, and usually possesses a peculiar heliotrope coloring often noted in disseminated lupus erythematosus. The eruption has been variously described as erysipeloid, roseolar, morbilliform, urticarial, eczematous and petechial, and may first appear after exposure to sunlight. In swift succession, manifestations of muscle disturbances follow. There are symmetrical muscle weakness, tenderness, swelling, brawny edema and pain on

active and passive motion. The patient may be rendered helpless. The muscles, firm and tense or soft and boggy, may be involved at a distance from the skin lesions. The skeletal muscles, especially those of the limbs, are chiefly affected, but in severe cases involvement of the muscles of deglutition, speech and respiration may result in symptoms resembling bulbar palsy. Splenomegaly is not uncommon. The temperature is usually remittent from a level of 101°F., but may exceed 103° or fever may be entirely absent. Tachycardia out of proportion to the temperature is often noted. An elevation of the white-cell count is usual, with eosinophilia in approximately one fifth of the cases. The urine often contains albumin, with pronounced creatinuria. The mortality averages 50 per cent, and death may occur from pneumonia, pleurisy or pericarditis. If the patient survives this stage, the edema subsides and the degenerative and inflammatory reactions in the muscles and skin may proceed to atrophy, fibrosis and contractures, especially at the elbows and knees. Osteoporosis occurs late, and the skin may take on a boardlike thickening identical with that observed in scleroderma. In mild cases, remissions or complete recovery may take place.

The pathology in the early stages, as determined by biopsy, is indistinguishable from that of early scleroderma. The skin, subcutaneous tissue and muscles are involved. The picture is one of edema, swelling of the endothelial cells lining the vessels, and perivascular and diffuse infiltration by lymphocytes and plasma cells.<sup>16</sup> Keil<sup>22</sup> has stated that in many cases of dermatomyositis the fundamental pathologic alteration occurs in the vasculature, with secondary implication of the muscle parenchyma. Numerous observers have expressed similar views, but there is no general agreement on this point. The muscle fibers present various disintegrative changes, ranging from swelling and loss of cross striations to vacuolar or hyaline degeneration. The similarity to the findings in thyrotoxicosis and myasthenia gravis has been noted.<sup>23</sup> According to Brock,<sup>24</sup> biopsy at a later stage in scleroderma shows thick-walled vessels, with the lumens narrowed or occluded, and an increase of the connective tissue in the sheaths and interstitial spaces of the muscles, with subsequent myosclerosis, whereas in dermatomyositis the cellular infiltration and degeneration of the muscle parenchyma itself persist to the end and the vascular changes are minimal. This observer found a diffuse increase in connective tissue in the heart at one post-mortem examination.

Various features of the disorder have suggested an inflammatory or infectious etiology.<sup>25</sup> The frequent occurrence of first symptoms after a fe-

brile disturbance such as tonsillitis and influenza, the fever, albuminuria and splenomegaly in some cases and the relapsing character of many cases all appear to point in this direction. Bacteriologic studies, however, have been almost uniformly negative. Keil<sup>22</sup> has discussed the factor of lead as a vascular poison in the pathogenesis of this and similar diseases, citing cases from his own experience and from the literature, but the evidence is based on association and analogy and is not entirely convincing. The concept that dermatomyositis may be a primary disturbance of the blood vessels was first proposed by Lépine,<sup>26</sup> who suggested the term "angiomyositis." Köster,<sup>27</sup> in a report of a series of cases with microscopic data, emphasized repeatedly the importance of the blood vessels in the pathogenesis of the condition. Fahr<sup>28</sup> also believed that in many cases of dermatomyositis the initial fundamental disturbances are in the blood vessels supplying the affected muscles, the alterations being a form of necrotizing arteriolitis. Equally significant is the relation of dermatomyositis to scleroderma. The cardinal pathologic alterations in the blood vessels and connective tissue of skin, muscles and other organs are considered identical in both conditions, although varying in degree and distribution.<sup>27, 29</sup> Other observers, however, do not agree with this opinion. Clinically, the evidence of a close relation is so impressive that many consider the two conditions as one disease. The literature since 1900 is replete with records of carefully observed cases diagnosed and reported as scleroderma, later assuming the classic feature of dermatomyositis, and the reverse has occurred even oftener.<sup>23-25, 30</sup> Many transitional cases are also reported.<sup>16, 21, 22</sup> In both diseases, a history of antecedent Raynaud's disease is common, edema is an initial symptom, joint pains are present, the pharynx and larynx may be affected, creatinuria is present, renal involvement with albuminuria may be evident, and calcification or pigmentation may occur. The diagnostic difficulties have been commented on by Brock,<sup>24</sup> who found that even biopsies were misleading until late in the disease. Without a biopsy of muscle the differentiation of dermatomyositis from trichinosis may be impossible. In the latter, involvement of the eye muscles and diaphragm occurs much more commonly than in dermatomyositis.

#### DISSEMINATED LUPUS ERYTHEMATOSUS

In his memorable reports of an "erythema group" of diseases with visceral manifestations, Osler<sup>31</sup> contributed greatly to the evolution of the present concept of systemic disease associated with

cutaneous manifestations. Of such syndromes, acute and subacute disseminated lupus erythematosus (as distinguished from the fixed and generalized discoid types) is a notable example. First described by Kaposi<sup>34</sup> in 1872, this disease shows a marked predilection for females, usually in the second to fourth decade of life. Nevertheless, cases have been reported in both sexes, at all ages and in many races and countries. Constitutional symptoms may far overshadow the cutaneous eruption, and often precede it for weeks or months. There may be a prolonged and insidious onset, with fatigue, exhaustion, disability, low-grade fever and joint pains, often diagnosed as rheumatoid arthritis or rheumatic fever. With the appearance of skin lesions or signs of visceral disturbances, the true nature of the serious underlying condition becomes apparent.<sup>35</sup> In the fulminating case, the constitutional and skin manifestations appear abruptly and simultaneously, the temperature exceeds 103°F, prostration is extreme, the sensorium is clouded, and stupor or delirium occurs. The dermatitis usually begins on the face or upper part of the thorax and neck as areas of indefinite superficial erythema that coalesce and become well demarcated. Edema of the eyes and face is often marked. There is rapid extension to the extremities, with involvement of the finger tips. The eruption, favoring the exposed surfaces, is bright reddish violet, often with a cyanotic tinge in the active areas. Petechial, purpuric, papillar or bullous lesions are seen, but indurated plaques with epithelial plugging, scaling and atrophy are rare. When involution occurs, residual pigmentation of various types may follow, and may simulate the extensive deep pigmentation of Addison's disease. Undue exposure to sunlight has precipitated the first appearance of the rash and an intensification of the constitutional reaction in a considerable number of cases. Local or generalized adenopathy is described. The systemic symptoms are almost infinite in variety. Involvement of the serous surfaces, including synovia, pleura, pericardium and endocardium, is common. Pain in the form of arthralgia, myalgia and neuralgia appears early and may be severe. Gastrointestinal symptoms vary from nausea, vomiting and diarrhea to crises of abdominal pain at times so marked as to result in surgical exploration. In a small proportion of the cases, the spleen is enlarged. In some cases, ophthalmoscopic examination reveals perivascular hemorrhages and fluffy exudates. Evidence of renal damage, with albuminuria, microscopic hematuria and casts, is a feature of the condition, but the blood pressure is usually not significantly elevated. Terminal

azotemia is frequently noted, and nephrotic syndromes have been described. The urinary findings are not consistently characteristic of any one type of renal lesion. There is often depression of the bone marrow, with secondary anemia, leukopenia and thrombopenia, a rise in the white-cell count usually signaling a serious and terminal complication. Serologic tests for syphilis may be falsely positive. Cultures of the blood have given equivocal results. The course in the acute fulminating cases is progressively downward, whereas in the more chronic types recession of the eruption and of the constitutional symptoms occurs only to be followed by an exacerbation months later. The mortality exceeds 90 per cent in the acute cases, and averages 50 per cent in the milder forms. Death may result from pneumonia, pericarditis, meningitis or uremia. The prognosis is indicated more accurately by the severity of the general reaction than by the extent of the cutaneous processes, which are helpful in diagnosis.

The characteristic pathologic features are found in the minute blood vessels, and consist of widespread proliferative changes in the endothelium, with a tendency to thrombus formation, or of a degenerative or necrotizing process in the walls, often with hemorrhage into adjacent tissues. These changes, however, are not specific for a <sup>57</sup>one disease. In disseminated lupus erythematosus, the changes in the skin are of minor importance and without diagnostic significance.<sup>30</sup> Thinning of the epidermis, atrophy of the sebaceous glands and hair follicles, edema of the cutis and marked dilatation of the superficial blood vessels and lymph spaces, with extravasation of blood and serum, are the essential findings. Most striking are the lesions in various organs throughout the body, especially the kidneys, heart, lungs, liver and serous surfaces. Considerable variability is seen in the general distribution of these lesions and in the viscera principally affected, but the kidney is most frequently involved. In gross these organs usually show little of significance, and have been discarded frequently without investigation. Microscopic study reveals hyaline thickening of many glomerular afferent vessels, with secondary thrombi, fibrosis and recanalization. The glomeruli themselves may be implicated, with a homogeneous thickening of the capillary wall described as a "wire-loop" effect.<sup>37-41</sup> At times a focal or diffuse panarteritis is found, with involvement of all the coats of the vessels, necrosis of the media, proliferation of the intima, secondary thrombi and periarterial accumulations of cells.<sup>42-44</sup> Stickney and Keith<sup>15</sup> found the renal arterioles to be essentially

normal in most of their cases, whereas the glomerular capillaries showed proliferation of the endothelial cells, hyaline thickening of the capillary walls and changes in the basement membrane, similar to the alterations in the toxemias of pregnancy, ulcerative colitis and peritonitis. Renal lesions were also noted by Snapper,<sup>40</sup> O'Leary<sup>47</sup> and Montgomery,<sup>48</sup> who commented on their similarity to the findings in eclampsia. In a considerable proportion of the cases, there is an endocarditis of varying type, with and without associated Aschoff bodies in the myocardium. Pericarditis, pleurisy, synovial changes, splenic infarcts, hepatic and gastrointestinal lesions, and terminal pneumonia constitute the remaining predominant changes seen post mortem.<sup>49</sup> On the other hand, Montgomery<sup>50</sup> was unable to discover any characteristic obliterative changes in the smaller blood vessels either in the internal organs or in the skin, and Mallory<sup>51</sup> has found no lesion that he considers pathognomonic of disseminated lupus erythematosus.

The etiology of the disease remains unknown. Innumerable theories have been advanced to explain its pathogenesis. Most observers favor the view that it is an infection, perhaps streptococcal, and others stress the relative frequency of a tuberculous background. Goeckerman<sup>52</sup> has considered it as a response to a septic infection conditioned by a previously established tuberculous allergy. O'Leary,<sup>53</sup> however, believes that the disorder is due to a toxemia, probably attributable to a bacterial agent. The frequent recovery of the tubercle bacillus in blood cultures, as reported by some investigators, has not been confirmed. Tuberculous adenitis is surprisingly prevalent. Streptococci of various types are often isolated in the terminal stages, but their primary role is open to doubt. The condition has been attributed to trauma in the form of drugs and heat, sensitivity to light, toxic factors, various metabolites, focal infection, disease of the bone marrow and disease of the reticuloendothelial system. Ludy and Corson<sup>54</sup> believe that the action of ultraviolet light in constitutionally susceptible people is a factor, and that a heavy metal like lead may serve as a catalyst. In almost half their cases, they found hematoporphyrinuria, but the attempts of numerous other investigators to detect this substance in the urine have been unsuccessful. The common observation that signs of a prolonged and severe systemic disturbance have antedated the appearance of the skin lesions indicates that sunlight can have only the secondary effect of determining the onset and localization of the dermatitis. The problem is whether disseminated lupus ery-

thematosis is a pathologic entity due to a specific if unknown cause, or whether it is a peculiar reaction of the internal organs and skin initiated by a variety of different agents. Madden<sup>55</sup> regards the various clinical forms as manifestations of one disease, differing only in the severity and distribution of the lesion. Denzer and Blumenthal,<sup>41</sup> recognizing that the vascular changes are the only conspicuous pathologic finding, nevertheless refuse to regard them as the sole basis of the disease and postulate an underlying more fundamental pathologic disturbance.

Although the disease is commonly considered as a problem for the dermatologist, the internist may see these patients first if the systemic complaints precede the onset of the dermatitis, if the skin eruption is mild and inconspicuous, or if the clinical course is fulminating, with severe constitutional symptoms. Diagnosis, as Mook and his associates<sup>58</sup> point out, is elusive and difficult. When the cutaneous manifestations predominate, a variety of skin diseases are simulated. If the systemic reaction is marked, typhoid fever, pyemia, malignant endocarditis and rheumatic fever must be considered. During crises of abdominal symptoms, surgical intervention for possible appendicitis, cholecystitis or perforated duodenal ulcer has seemed imperative.

The relation of systemic lupus erythematosus to dermatomyositis, and less directly to scleroderma, is suggested and supported by both clinical and pathological evidence. Raynaud's phenomena may precede or accompany the disease in all three. Subcutaneous calcification and pigmentation on the exposed surfaces, reaching Addisonian intensity, may occur in all three. There is hypersensitivity to sunlight with aggravation of the condition in both systemic lupus erythematosus and dermatomyositis. There are numerous reports<sup>19, 56</sup> in the literature, of which only a few are cited, describing cases diagnosed as disseminated lupus erythematosus by one or more competent dermatologists and later showing the typical features of dermatomyositis. Turner<sup>57</sup> reported a definite case of dermatomyositis that in a recurrence exhibited the skin lesions and constitutional symptoms of lupus erythematosus disseminatus. Montgomery<sup>58</sup> has also pointed out the clinical similarities of these two conditions. Dowling<sup>59, 61</sup> considers that the vascular changes of scleroderma and dermatomyositis are of the same order, and much like those of disseminated lupus. Visceral lesions, with involvement of the smaller blood vessels, occur in all three conditions.

## • THE LIBMAN-SACKS SYNDROME

First described in 1924, the features of the Libman-Sacks<sup>58</sup> syndrome were listed as prolonged fever, an atypical verrucous endocarditis, absence of Aschoff bodies in the myocardium, white-centered petechiae in the skin, signs of renal disease and consistently negative blood cultures. In several patients, skin lesions indistinguishable from those of disseminated lupus erythematosus were noted. In 1931, Baehr,<sup>59</sup> discussing the renal lesions seen in 17 cases, reported that unusual vascular changes were found not only in the kidneys but in other internal organs, and that most but not all cases had skin manifestations characteristic of disseminated lupus. The syndrome then included pleural effusion, pericarditis, arthritis and leukopenia. By some observers it was considered as a separate entity; others regarded it as one of Osler's erythema group, and a few included it in the many variables of subacute disseminated lupus erythematosus. In a subsequent paper Baehr<sup>49</sup> detailed the clinical and pathological data in 23 cases of disseminated lupus, in 13 of which the coarse verrucous endocarditis of the Libman-Sacks syndrome without Aschoff bodies was found. Twenty of these cases presented disseminated vascular lesions in the kidneys and other viscera. It was then apparent that endothelial damage, which might involve the valvular endocardium or not, was the outstanding feature of this group of cases, and the unusual endocarditis that originally drew attention to the syndrome assumed a position of secondary importance. In his pathological studies of systemic lupus, Montgomery<sup>48</sup> found endocarditis in 7 of 15 cases, in each one associated with Aschoff bodies in the myocardium. Belote and Ratner,<sup>60</sup> Denzer and Blumenthal,<sup>41</sup> Keil<sup>61</sup> and Montgomery<sup>56</sup> have identified the Libman-Sacks syndrome more or less definitely with disseminated lupus erythematosus. It is of interest that it has never been reported in scleroderma or dermatomyositis.

## POLYARTERITIS NODOSA

Under the name "periarteritis nodosa" a voluminous literature has accumulated concerning a disease characterized by widespread segmental lesions in the smaller arteries and arterioles. Occurring at all ages, but most commonly between ten and forty, the condition affects males four times as frequently as females. The onset may be abrupt or gradual, with fever, muscular pains, general weakness, abdominal pain and edema. The temperature reaches 101°F., may be constant

or intermittent, and is associated with a tachycardia out of proportion to the temperature level. Polymyositis in the extremities and polyneuritis of peripheral type are common. Cramplike or colicky abdominal pain occurs in most cases. Nodules, firm and nontender, may appear in the later stages along the course of superficially placed arteries and thus establish the diagnosis on clinical grounds or by biopsy. Cutaneous lesions of many types are described. Leukocytosis, secondary anemia and albuminuria, with microscopic hematuria and casts, are almost constant features. Hypertension is a relatively late manifestation and is usually of renal origin. Later, there is cardiac failure without obvious cause, and bronchiolitis with prominent cough. The presenting symptomatology has been grouped as renal, abdominal, neuromuscular, cardiac and bronchial. The duration of the disease is usually measured in months, and the prognosis is extremely unfavorable.

With the recognition that the media rather than the adventitia was the primary seat of the lesion and that all the coats of the vessels were involved, Haining and Kimball<sup>62</sup> proposed the name "polyarteritis nodosa." In addition to inflammatory changes in the adventitia, Leishman<sup>63</sup> described necrosis of the media, rupture of the internal elastica lumina, proliferation of the intima and thrombosis, at times with recanalization. In the early stages, the characteristic local cellular reaction is a polymorphonuclear one, with a large percentage of eosinophils.<sup>64</sup> In order of frequency, the organs involved are the kidneys, heart, liver, spleen, lungs, mesentery, skeletal muscles and nervous system. O'Hare and his associates<sup>65</sup> have noted the resemblance of the pathology to that of the rickettsial diseases. Fahr<sup>28</sup> considered that the arteriolitis of dermatomyositis might be allied to that of periarteritis nodosa.

Suggestions concerning etiology include streptococci, syphilis, parasites, viruses and allergic factors. Two opposing schools of thought are exemplified by Moschowitz,<sup>66</sup> who maintains that periarteritis nodosa is not a primary clinical or morphologic entity but a complication of various widely divergent conditions, and by Haining and Kimball,<sup>62</sup> who, believing that it is due to a specific infection, possibly with a virus, point out that if it is a manifestation secondary to infection it should occur much oftener.

#### DISCUSSION

It is evident from the descriptions of these diseases that a differentiation on a clinical basis should be possible in most cases.

In scleroderma, there is a preponderant incidence in the fourth and fifth decades and in women; antecedent vasomotor disturbances in one third of the patients; the triad of edema, induration and atrophy of the skin; arthritic manifestations, localized osteoporosis and secondary atrophy of voluntary muscles; absence of fever or other constitutional symptoms until late; and a chronic course, with relatively favorable prognosis. Although changes in the small arterioles and proliferation of the connective-tissue stroma may be found throughout all the viscera and in many of the muscles, resulting systemic disturbances that can be detected clinically are relatively uncommon.

Dermatomyositis occurs more commonly in children as well as later in life, is preceded by prodromal symptoms, and presents a diagnostic triad of edema, dermatitis, with sensitivity to sunlight, and myasthenia. Muscular pain, tenderness and swelling are common. A constitutional reaction is evidenced by fever, tachycardia, albuminuria, leukocytosis, occasional eosinophilia and splenomegaly. The prognosis is guarded, with an average mortality of 50 per cent. The pathologic changes involve the small blood vessels and the musculature, the skin being secondarily affected in the typical cases.

Disseminated lupus erythematosus is seen classically, although not invariably, in females of the second to fourth decade, and is characterized by constitutional symptoms of smoldering or fulminating intensity that precede, follow or appear abruptly with the cutaneous eruption. As in dermatomyositis, exposure to sunlight may aggravate or initiate both the rash and the general symptoms. The prostration, fever, tachycardia, arthralgia, gastrointestinal symptoms and involvement of serous surfaces, together with evidence of renal disturbance and depression of the bone marrow, all indicate the severity of the systemic reaction. The ultimate prognosis is poor. The pathologic changes, which remain the subject of much controversial discussion, are not peculiar to this disease. There are widespread proliferative changes in the endothelium of the minute blood vessels, at times with degenerative or necrotizing processes in the walls, varying considerably both in intensity and in distribution in individual cases. In some patients, involvement of the endocardium with an atypical verrucous process has led to the description of the Libman-Sacks syndrome.

Polyarteritis nodosa is seen most commonly between the ages of ten and forty, and in males much more frequently than in females. The general systemic disturbance is characterized by fe-

ver, myalgia, leukocytosis, abdominal pain and renal involvement, with albuminuria, microscopic hematuria and casts. Cutaneous lesions may occur, but are easily distinguished from the eruption of dermatomyositis and disseminated lupus erythematosus. In some cases the appearance of nodules along the course of superficial arteries settles the diagnosis. The pathologic lesions consist of a segmental involvement of the small arteries and arterioles that starts usually in the media, involves all the coats of the vessels and leads to a characteristic local polymorphonuclear cellular reaction, with a large percentage of eosinophils. The kidneys are most markedly affected. The disease runs a downward course over a period of months.

Efforts to group the various conditions discussed in this report under the heading of diffuse vascular disease or mesenchymal disease have been criticized as an attempt at oversimplification that does not actually contribute to an understanding of the fundamental pathogenesis of these disorders. Differences do exist in the extent of the pathologic changes, the size of the vessels involved, the organs chiefly affected and the resultant clinical picture. Nevertheless, if it is recognized that the classification is a broad and tentative one, there can be no serious objection.

Three important and perplexing questions arise in a survey of these diseases. What is the essential significance of the changes in the blood vessels? What agents or mechanisms bring about these alterations? Are various members of this group different clinical manifestations of the same disease? One enters immediately on highly controversial ground.

Although the vascular pathology must be considered the most constant histologic finding, in many cases the changes are so slight and the distribution so limited that they scarcely explain the varied clinical pictures and the frequent fatal results. Occasionally no blood vessel alterations whatever can be demonstrated, so that Mallory<sup>51</sup> and others have come to believe that there is no pathognomonic pathology in systemic lupus erythematosus and similar conditions. A conservative attitude, such as that of Denzer and Blumenthal,<sup>52</sup> seems best—namely, that the vascular lesions are merely a manifestation of an underlying pathologic process that in its progress frequently leads to morphologic changes in the small blood vessels.

Equally obscure are the etiologic agents causing these changes, and the mechanism by which the effects are produced. The very multiplicity of suggested factors indicates the confusion that surrounds this problem. The role of constitutional

susceptibility is repeatedly stressed in the literature. An example of this concept is seen in systemic lupus erythematosus, which is attributed by some to a response to a streptococcal infection in a patient previously sensitized by tuberculous allergy. The possibility of some form of toxemia is given impetus by the similarity of the renal lesions to those found in some cases of eclampsia. Various observers maintain that these diseases are distinct entities produced by specific if unknown causes, and point out the resemblance of the vascular lesions to those seen in rickettsial diseases, such as typhus. On the other hand, it is generally agreed that polyarteritis nodosa can be a sequel to a number of infectious and toxic conditions.

Most disconcerting have been the cases, diagnosed by careful clinicians as typical of one disease, that have progressed and assumed the classic clinical and histologic features of another in the group. Many of these transitional cases are reported. The logical consequence of this transition has been the tendency to identify dermatomyositis with scleroderma, and disseminated lupus erythematosus with dermatomyositis. Since the diagnosis must almost always be a clinical one without the confirmation that laboratory tests might give, it is probable that most of these cases represent diagnostic errors demonstrated with the passing of time. All the diffuse vascular diseases possess many symptoms and signs in common, and the placing of undue emphasis on any one of these may lead to unwarranted interpretations and conclusions. It is clear that in the final stages, dermatomyositis may be associated with the atrophic cutaneous changes of scleroderma, and that advanced scleroderma may include the extensive muscle atrophy and degeneration seen in dermatomyositis. Most of the confusion between the latter condition and systemic lupus erythematosus has arisen from the character and distribution of the rash and the associated myasthenia. Until further information is available, it seems best to consider these several diseases as clinical entities and to regard a diagnosis in the early phases as only tentative.

#### SUMMARY

Clinically, there are characteristic syndromes that correspond to the diagnostic terms of scleroderma, dermatomyositis, disseminated lupus erythematosus and polyarteritis nodosa. Not infrequently, however, patients present symptoms and signs that form essential characteristics of two or more of these conditions.

Since the diagnosis is almost always a clinical one without laboratory confirmation, the placing of undue emphasis on certain features may lead

to diagnostic errors and a tendency to identify one disease with another.

There is no unanimity of opinion regarding the specific and fundamental pathology of certain of these syndromes, all of which represent a widespread vascular involvement, differing usually in the extent of the pathologic change, the size of the vessels involved, and the organs chiefly affected.

## TUBERCULOSIS OF THE STERNUM\*

JOSEPH D. WASSERSUG, M.D.†

MIDDLEBORO, MASSACHUSETTS

**T**UBERCULOSIS rarely involves the sternum. In 1134 cases of bone and joint tuberculosis admitted to the Lakeville State Sanatorium from 1926 to 1940, the diagnosis of tuberculosis of the sternum was made in only 12, an incidence of 11 per cent. References in the literature consist essentially in a few isolated case reports<sup>1,2</sup>

symptom in 7 cases, whereas pain was an early symptom in only 3. In 2 cases a discharging sinus was the chief complaint.

Eventually, practically every case develops one or more draining sinuses, and in about a third of the cases the sinuses are multiple. Figure 1 depicts the general distribution of these sinuses. It can readily be seen that any portion of the sternum or its adjacent structures may be involved, hence, the exact location of these sinuses is of no diagnostic significance.

Careful study of the material discharging from

FIGURE 1 *Approximate Distribution of Sinuses in Patients with Tuberculosis of the Sternum*

This paper presents a study of these 12 cases, 9 of which were followed for an average of more than five years.

The 12 cases were about equally divided as to sex: 7 females and 5 males. The ages of the patients at the onset of symptoms varied from one and a half to seventy years, and there was no preponderance of any age group. In no case was there a history of trauma. There was a definite history of contact with tuberculosis, however, in 5 cases.

Tuberculosis of the sternum must be suspected when a patient who has a tuberculous focus elsewhere in the body develops a swelling on the anterior chest wall. Eleven of the 12 patients had other tuberculous lesions. A painless swelling in the region of the sternum was the presenting

oculation. In 8 of the cases, such material confirmed the diagnosis of tuberculosis: 2 by guinea-pig test alone, 2 by biopsy alone and 4 by both methods. In 4 cases, the diagnosis was made only on clinical and roentgenographic evidence.

Tuberculosis of the sternum must be differentiated from tuberculosis of the chest wall and tu-

coma of the sternum may simulate tuberculosis roentgenographically, according to Cella Maggani,<sup>4</sup> but since the sternum is readily accessible surgically, a biopsy specimen should be taken whenever there is the slightest doubt. Other tumors, such as cysts, lipomas and fibromas, may also be ruled out by biopsy.

1	F	17	Discharge	Incision and drainage	No	Trochanter Kidney	Followed 2 10/12 years, no recurrence of disease of sternum.
2	M	10	Swelling	Incision and drainage, curettage, and biopsy	Yes	Lymph nodes Spine	Discharged in poor condition at parent's request, followed 2 7/12 years, then lost (probably dead).
3	F	10	Discharge	None	No	Lymph nodes Spine Lungs	Had one sinus which stopped draining one week after admission, followed 11 3/12 years, no recurrence of sternum disease, works as nurse.
4	M	19	Swelling	Aspiration	No	Ankle Lungs Bowel	Left at own request against advice; had two sinuses died 3 8/12 years later of pulmonary tuberculosis
5	F	67	Swelling	None	Yes	Ankle	Sinus healed 2 years after discharge, patient later developed Pott's disease; followed 4 3/12 years, died of arteriosclerosis in an insane asylum.
6	M	22	Swelling	Aspiration	Yes	Finger Lungs	Had four sinuses in all, has not worked since discharge, followed 3 7/12 years, has far advanced pulmonary tuberculosis at present.
7	F	70	Swelling	Incision and drainage	Yes	Lymph nodes Ribs Pleura Lungs	Died 7 months after admission, autopsy revealed extensive tuberculosis of chest and arteriosclerosis
8	F	40	Swelling	Excision of costal cartilage	Yes	Lymph nodes	Sinus healed 7 months after admission, followed 10 5/12 years, has had no recurrence of sternum disease.
9	F	26	Pain	Aspiration and resection of sinuses	Yes	Chest wall Peritoneum	Followed 10/12 years, slight drainage period from three pin point sinuses
10	M	56	Pain	Incision and drainage, and biopsy	Yes	None	Left at own request against advice, followed for 7 4/12 years, no recurrence of disease at sternum, bedridden past 3 years
11	M	46	Pain	Curettage	Yes	Spine	Still hospitalized, has open granulating wound over manubrium, with purulent drainage.
12	F	1½	Swelling	None	No	Finger Spine Lungs	Still hospitalized, sinuses are healed

berculosis of the ribs and costal cartilages.<sup>3</sup> Tuberculosis may also involve the lymphatic vessels situated in the anterior costal interspaces, as well as the internal mammary or sternal lymph nodes, and necrotic nodes in this area may give rise to abscesses. In female patients, tuberculosis of the breast must occasionally be considered. The injection of a radio-opaque substance under such circumstances readily gives the clue to the actual process. A negative tuberculin test helps to distinguish chronic nontuberculous osteomyelitis of the sternum from tuberculosis and is therefore of value. Syphilis can be identified by the Wassermann test and by the fact that syphilitic lesions usually heal rapidly with specific treatment. Sar-

In 25 per cent of the cases, the tuberculosis of the sternum became arrested spontaneously and the sinuses healed. In the remaining 75 per cent, a variety of operative procedures were performed, such as aspiration, incision and drainage, curettage and the resection of sinuses. Since these operations were performed by different surgeons in different hospitals, accurate evaluation is difficult. Aspiration was performed in 3 cases, in two of which further operation was unnecessary; in the third, resection of sinuses was performed later. Herrick<sup>1</sup> also reported a patient in whom aspiration was performed and whose lesion healed under conservative treatment. In the other cases, incision and drainage were done at least four times.

nd curettage at least twice. The operative end results were usually good, regardless of the procedure followed.

With the aid of social service, a follow up was possible in all the cases discharged from the sanatorium. Two patients in this series (Cases 11 and 12) are still hospitalized, and a third (Case 13) died while in the sanatorium. Autopsy in this last case revealed tuberculosis of the sternum, ribs, pleura, pericardium, mediastinum and anterior chest wall. Of the 9 discharged patients, 2 (Cases 4 and 5) have died, one of pulmonary tuberculosis, and the other of arteriosclerosis. In neither was there recurrence of the disease in the sternum. A third patient (Case 2), a Chinese boy in ex-

no swelling, pain or tenderness. One of the patients (Case 6), however, has far advanced pul-

FIGURE 3 Lateral View of Manubrium (Case 11)

tremely poor condition, was taken by one of his parents to China and probably died en route.

Six cases were followed from ten months to eleven years and three months, with an average of over six years. In only one patient (Case 9), followed only ten months, does slight drainage persist. None of the other patients have had any recurrence of the disease in the sternum. All sinuses have remained healed, and there has been

FIGURE 4 Lateral View of Xiphoid Process (Case 10)  
Note the irregular contour and the areas of apparent bone destruction

monary tuberculosis, and another (Case 10), has been bedridden for three years because of a cerebral hemorrhage. In no fatal case in this series could tuberculosis of the sternum be regarded as a cause of death.

#### SUMMARY AND CONCLUSIONS

Twelve cases of tuberculosis of the sternum are reviewed. Sternal tuberculosis is almost invariably secondary to other demonstrable tuberculous foci. Painless swelling in the region of the sternum is the usual presenting symptom. The end results of conservative treatment are consistently good, radical surgery is apparently unnecessary.

Herrick<sup>1</sup> also reported a patient in whom aspiration was performed and whose lesion healed under conservative treatment. In the other cases, incision and drainage were done at least four times

restless,  $\frac{1}{2}$  gr and, 30 minutes later,  $\frac{1}{2}$  gr of morphine were given subcutaneously, with very little effect. During the afternoon he continued to be very restless, and uncooperative, whereas he ordinarily behaved well. In the late afternoon he began to vomit and hiccough and he continued to vomit during the next 36 hours. At 9:00 p.m., 2 gr of luminal sodium was given intramuscularly with no effect. At 11:00 p.m., the mistake in the strength of the solution not having been discovered, 10 gm of sodium sulfapyridine was given intravenously.

On November 29, restlessness became even more marked, and at 2:00 a.m. another 2 gr of luminal sodium was given intramuscularly. At 4:00 a.m., 1 cc of paraldehyde was given intravenously in an attempt to quiet the patient, but was absolutely without effect. At 7:00 a.m., 30 cc. of paraldehyde was given by rectum with slight sedative effect. At no time were convulsions or gross muscular twitching observed, and the patient was always clear mentally. He stated that he could not lie still. At 7:30 a.m., it was noted that the urine was dark and smoky. Examination of this specimen showed it to contain innumerable red cells and acetyl sulfapyridine crystals. Since a sample of serum contained no hemoglobin, no acute hemolytic process was present. During the morning the error in dosage was discovered and large amounts of intravenous fluids were started. During the next 24 hours, the patient received 6500 cc. of 5 per cent dextrose in distilled water, and 1000 cc of 5 per cent dextrose in saline. The urine continued to be grossly bloody but he voided 1560 cc.

On November 30, during the early morning hours the patient began to feel better and slept intermittently. The vomiting had ceased, although he was still somewhat nauseated, and the restlessness had largely disappeared. During the 24 hours he received 2500 cc of 5 per cent dextrose in distilled water and 1000 cc of 5 per cent dextrose in saline. The urine output was 3100 cc. In the afternoon, the urine was no longer grossly bloody, although microscopic blood was still present. On December 1 the major complaint was lower abdominal pain, which was relieved by bladder irrigations of distilled water. It was thought that the discomfort was due to a chemical cystitis. This pain gradually subsided during the next few days.

On December 3 moderate jaundice was first noted and the patient complained of some right upper quadrant pain. The lungs were clear. After the administration of sulfapyridine, the temperature had not risen over  $101^{\circ}\text{F}$  and over the course of several days it gradually fell to normal. Because of the jaundice, he was given intravenously 2000 cc of 10 per cent dextrose in distilled water daily for the next 5 days.

The jaundice gradually subsided and was not visible on December 10. No leukopenia, significant fall in the number of granulocytes or drop in hemoglobin occurred. Improvement was steady, and the patient was discharged on December 17 feeling quite well.

On February 29, 1941, he was seen by one of us (F.B.C.) and reported that he was feeling fairly well but had not yet regained full strength. Physical examination was negative. No jaundice was evident and the liver edge could not be felt. A complete blood examination

was entirely negative. A urine specimen had a specific gravity of 1.025, and was negative for sugar and albumin. Microscopic examination of the sediment, after centrifuging, revealed no casts or red cells. Two to four white blood cells per high power field were present, probably the result of a low grade bladder infection following the previous bladder irrigations. Chemical examination of a portion of the urine specimen for sulfapyridine was negative. The blood urea nitrogen was 13 mg per 100 cc.

In Figure 1 some of the laboratory findings are charted. Unfortunately, no blood was taken for drug determination until 10 hours after the second intravenous dose. At that time there was still 207 mg of free and 290 mg of total sulfapyridine per 100 cc of blood. The method employed

FIGURE 1

was that of Bratton and Marshall,<sup>3</sup> using a 1:75 dilution of the blood, after standardization for sulfapyridine on the Cenco photometer. The free drug had been excreted 57 hours after the last administration, although traces of acetyl sulfapyridine were still present 81 hours after the second dose.

### SUMMARY

The patient in this case, suffering from post-operative pneumonia, received, through an error, 30 gm of sodium sulfapyridine intravenously in a ten hour period. He survived probably because of his youth, good kidney function and the prompt administration of large amounts of intravenous fluids. Convulsions, muscular twitching and anuria were not observed, but marked restlessness and irritability, gross hematuria and jaundice were strikingly evident.

## GUMMA OF THE FRONTAL BONE

## Report of a Case

NICHOLAS P. COSCO, M.D.

MIDDLETOWN, NEW YORK

**F**EW general practitioners who have occasion to treat late syphilis have an opportunity to watch a definite lesion clear up dramatically under treatment. Frequently the wisdom of intensively treating such cases is questionable, in view of reactions. The following case of gumma of the frontal bone completely resolved under antisyphilitic therapy that could by no means be called intensive. Furthermore, it illustrates that the titer of

skin edges were widely undermined to the mid forehead, beyond the hairline, to the zygomatic arch and into the upper lid. The temperature, pulse and respirations were normal. Examination of the urine was negative. Hospitalization was advised and promptly refused. A blood serologic test, culture and biopsy, suggested as an alternative, also met with refusal. The patient insisted that all he wanted was "some salve and something for the pain." Believing that he might possibly feel differently later, I applied zinc peroxide paste to the lesion; codeine was prescribed for the pain, and the patient was told to

FIGURE 1. X-Ray Films Taken March 4, 1938.  
A is the anteroposterior view; and B, the lateral.

a serologic test for syphilis may remain exactly the same in spite of a dramatic clinical result.

## CASE REPORT

G.D., a gas-station attendant, had first consulted a physician on December 25, 1937, because of pain and swelling in the right forehead after a glancing blow several days previously. Hot compresses were advised, and 24 hours later the area was incised. According to the patient, "quite a lot of pus came." The lesion was dressed daily, but evidently became progressively worse.

I was first consulted on February 4, 1938. At that time, a draining, ulcerated lesion about the size of a half dollar was found just above the right eye. The upper right lid was edematous, and the eye was completely closed. Bare bone could be detected at the base of the ulcer. The

return on the next day. However, he did not return until March 4.

In the meantime, the pathologic process had gone from bad to worse. Practically the entire right forehead had become ulcerated, and the pain was intense. The temperature, pulse and respirations were still normal. Although the patient continued to refuse hospitalization, he agreed to permit certain procedures. X-ray films of the right frontal region and blood for a serologic test for syphilis were then taken. Smears of the lesion were negative for tubercle bacilli. The patient was placed on 15 gr. of potassium iodide empirically, the lesion was cleansed, and a dry sterile dressing was applied. The test for syphilis was reported as positive in a titer greater than 1:10. The x-ray films (Fig. 1) were reported as follows by Dr. James W. Walton, of the Horton Memorial Hospital:

Radiographic examination reveals an area of disease in the right frontal bone extending down to the zygomaticofrontal suture, backward almost to the frontoparietal suture and medially almost to the mid line. The lesion is approximately 7.5 cm in diameter, with densely sclerosed edges and an area of rarefaction in the center measuring at least 2.5 cm in diameter. This area is very circumscribed and has very densely sclerosed edges, and because of its location, could be a gumma. If a definite history of injury some time ago can be obtained, chronic osteomyelitis must be considered, but there is more sclerosis than is usually seen in this condition.

The dose of potassium iodide was immediately increased to 30 gr, and protoiodide of mercury was administered in

Clinically, the lesion had entirely healed with the exception of a small area about 3 mm in diameter. This cleared up about 2 weeks later.

Treatment was continued until July 30, but during the entire course of the disease the patient received only ten injections of Mapharsen and eleven of Bismarsen. Repeated serologic tests for syphilis remained positive, with a titer greater than 1:10.

The patient was seen on March 1, 1940, for another complaint, and at that time, with the exception of a barely noticeable amount of puckering, nothing remained of the original lesion.

Although not many cases of gumma of the frontal bone have been reported, the lesion is

A

B

FIGURE 2 X-Ray Films Taken June 17, 1938  
A is the anteroposterior view and B, the lateral

doses of  $\frac{1}{4}$  gr three times daily. Within 48 hours, the pain was relieved. On March 9, the patient was started on small doses (0.2 gm.) of Bismarsen. Mapharsen was instituted on March 24.

The x-ray report on April 18 was as follows:

Radiographic re-check of the right frontal bone shows very extensive resolution of the area of sclerosis with central destruction—apparently a gumma—previously reported. The smaller areas previously reported also show considerable resolution.

The clinical appearance of the lesion had also been markedly changed. The edema of the right upper lid had disappeared, the drainage had ceased, and granulation tissue had appeared. Most important of all, the soreness had entirely disappeared. Antisyphilitic therapy was continued, with a shift to 0.2 gm. doses of Bismarsen on June 6, but only dry sterile dressings were applied to the wound.

The last x-ray films (Fig 2) were taken on June 17, and were reported as follows:

Radiographic re-check of the right frontal bone shows complete resolution of the area referred to in previous examinations (Fig 1). There is moderate bone sclerosis in this area.

not generally considered rare. Most patients seem to do well, but complications occur in the underlying structures, and deaths have been reported. In the diagnosis, the most important feature is to think of the possibility of and to take a specimen for a serologic test for syphilis in all open lesions. This case is of further interest in that the therapy was not too intensive because the patient would not co-operate, the blood titer remained unchanged, and yet the lesion responded dramatically.

#### SUMMARY

A case of gumma of the frontal bone is presented, and the importance of serologic tests in all such open lesions is stressed. Antisyphilitic therapy brought about complete resolution of the lesion, even though the serologic titer remained exactly the same.

BOSTON

VITAMIN E AND CERTAIN DISEASES OF THE  
NERVOUS AND MUSCULAR SYSTEMS

**T**WO diseases have come into prominence during the last two years because of possible successful treatment by vitamins, and especially by vitamin E: namely, amyotrophic lateral sclerosis and progressive muscular dystrophy.

Before the effect of treatment is discussed, a few words about diagnosis are in order. Progressive muscular dystrophy is generally considered a slowly progressive disease in which muscle-fiber wasting is the prime factor, and replacement by fat a secondary manifestation. No causative lesions are found in the central or peripheral nervous system. In the typical advanced case, there is little difficulty in making a diagnosis; in the early stages and in atypical cases, diagnosis is often in doubt for months or years. Amyotrophic lateral sclerosis, when conforming to the original Charcot description, is a disease of the spinal cord in which the latter shows, anatomically, degeneration of the anterior-horn cells and pyramidal tracts bilaterally, with no evidence of inflammation, compression or vascular disturbance. Clinically, the patient shows weakness, with atrophy of the muscles, usually beginning in the hands, and spasticity, usually beginning in the legs; the two processes relentlessly extend in intensity and in parts involved, and end in bulbar palsy.

Amyotrophic lateral sclerosis in its early stages and even later also simulates a number of other conditions, so that most neurologists advisedly make the diagnosis of "amyotrophic lateral sclerosis syndrome." Later developments show that a large number of these patients do not run the course of the typical Charcot description. Rubenstein<sup>1</sup> has recently emphasized this point: of 8 cases studied, only 4 were typical; the other 4 afforded evidence that somatic disease caused a clinical picture similar to that of the disease under consideration.

The difficulties in diagnosis must be kept constantly in mind before one accepts at face value the results of treatment in these two diseases. And

yet it is fair to say that when the clinical picture is such that either diagnosis has been seriously entertained, the outlook for recovery is not good, and any agent that will arrest the process should therefore be welcome, whatever the exact diagnosis.

In 1939, at the International Neurological Congress at Copenhagen, a paper by Einarson and Ringsted<sup>2</sup> on vitamin E stimulated interest. They observed atrophy and spinal-cord degeneration in rats as a result of vitamin E deficiency. In 1940, Bicknell<sup>3</sup> published a paper reporting such encouraging results in dystrophy that he makes this bold statement, "The discovery of the importance of vitamin E in the treatment of muscular and nervous diseases appears to be revolutionary." He claims improvement in 12 cases of progressive muscular dystrophy out of 13 treated for six weeks or more. Of 4 cases of amyotrophic lateral sclerosis, 2 were improved, and 2 died with bulbar paralysis. His treatment was 15 gm. of dried whole-wheat germ twice daily by mouth. His case reports are meager, frequently only a few lines, and improvement was often admittedly dependent on report rather than personal evidence. On the basis of evidence given, it is difficult for one to reach the optimistic conclusions quoted above. Stone<sup>4</sup> is also encouraged by treatment of pseudohypertrophic muscular dystrophy and of myotonia congenita. Wechsler<sup>5, 6</sup> undoubtedly is chiefly responsible for stimulating interest in vitamin E in the United States. In his later paper, he analyzes 20 of his 30 cases of amyotrophic lateral sclerosis. He admits a difficulty in diagnosis but believes that vitamin E is especially successful in the degenerative type. He used alpha-tocopherol acetate by mouth, up to 50 mg. daily, and intramuscular injections of this drug in oil; he also gave 2 teaspoonfuls of wheat-germ oil by mouth. Vitamin B complex and a vitamin-rich diet were also given. Two patients recovered, 4 showed marked improvement, and 6 improved somewhat.

A number of other papers on this subject have been published during the past year, some strongly in favor, others giving negative results of treatment. Papers written from four large clinics—Cornell, Columbia, Mayo and Harvard—uni-

All articles in this series will be published in book form; the current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

\*Professor of neurology, Harvard Medical School; chief of the Neurological Service, Massachusetts General Hospital.

formly show poor therapeutic results. Denker and Scheinman,<sup>7</sup> using even larger doses of vitamin E than those recommended by Wechsler, assert, on the basis of 15 patients, that "no therapeutic results of any value were observed." Ferree et al.<sup>8</sup> state that "vitamin E and vitamin B<sub>12</sub> preparations, given in large amounts, failed to influence the course of either amyotrophic lateral sclerosis or muscular dystrophy in a series of patients followed for a period of two to twelve months." Workers at the Mayo Clinic<sup>9</sup> and at the Neurological Unit of the Boston City Hospital<sup>10</sup> are likewise unimpressed.

At a meeting of the Boston Society of Psychiatry and Neurology in April, reports were made from the Boston City and Massachusetts General hospitals, and the conclusions reached and the discussion were pessimistic. However, in chronic diseases, with the diagnostic difficulties mentioned earlier, one should not judge too quickly a therapy that has the support of men of the standing of Wechsler.

The best results have been obtained in the treatment of dystrophy in children; the worst results have been in cases of bulbar palsy. Another year should determine the value of this form of treatment.

#### BASILAR ANOMALIES AND THE ARNOLD-CHIARI MALFORMATION

For many years, malformations of the occiput, atlas and axis have been recognized as interesting anomalies. Knowledge of the displacement of medulla, cerebellum and spinal cord, commonly known as the "Arnold-Chiari malformation," goes back to 1894 and 1895.

Recently, there have been attempts to establish a relation between these anomalies, one of bony development, the other of the central nervous system. Although the two conditions occur independently of each other, there appears to be a developmental relation. The symptomatology is similar enough to include both conditions in comparative discussion. To be thoroughly inclusive in a clinical differentiation at this level, one should also consider syringomyelia and high cervical-cord tumor.

An extremely lucid and well-illustrated paper on the bony anomalies of this region is that of List.<sup>11</sup> He explains the anomalies on a basis of abnormal fetal development and incorrect ossification, with subsequent modification by rickets, weight bearing and so forth. He recognizes in his cases four types of deformity: malformation of the occipital foramen and basilar impression (platybasia); fusion of the atlas with the occiput

and malformation of the atlas; fusion of other cervical vertebrae and malformation of these vertebrae; and abnormal position of the axis in relation to the occiput and atlas. These anomalies may be considered essentially benign, but with continued growth and under stress, neurologic symptoms may arise. The chief interest concerns platybasia, in which the basiocciput is thinned and mushroomed upward by the atlas, and the foramen magnum is narrowed. The medulla resting on this floor is thus compressed anteriorly and constricted in its passage through the narrowed foramen magnum. The neurologic picture is naturally one of medullary compression, and when the fluid pathways become obstructed, of super-added hydrocephalus. If in the advance of the process, dislocation of the axis on the atlas occurs, upper cervical-cord symptomatology is to be expected.

The Arnold-Chiari deformity concerns the nervous system. The medulla and cerebellum are displaced downward through an enlarged foramen magnum into the cervical canal. In the case reported by Penfield and Coburn,<sup>12</sup> the cerebellum extended to the third cervical vertebra. Such a displacement leads to medullary jamming in the foramen magnum, with extreme traction on the lowest cranial-nerve roots and with cerebellar symptoms, and additional symptoms of increased intracranial pressure. The mechanism by which this downward herniation of the brain through the foramen magnum occurs is not always clear, but in Penfield's case it was satisfactorily explained as follows: in childhood, the patient had been operated on for a mid-dorsal meningocele; at autopsy, the dura and consequently the spinal cord and nerve roots were firmly adherent at the point of operation. It seemed apparent that this attachment prevented the normal ascent of the cord in the spinal canal with growth, and consequently the upper portions of spinal cord, medulla and cerebellum were slowly drawn down. This mechanism is probably not the only possibility in explaining the downward displacement, for in some cases there is no meningocele. Adams and his associates<sup>13</sup> have studied a case of this type, without evidence of meningocele. An operative decompression so completely relieved the symptoms that the patient returned to work.

Although points of clinical differentiation are made between platybasia and the Arnold-Chiari malformation, both conditions produce slow pressure on the medulla, cerebellum and low cranial nerves, and both conditions must be considered in lesions that indicate an abnormality near the foramen magnum. Furthermore they must be differen-

Amyotrophic lateral sclerosis, when conforming to the original Charcot description, is a disease of the spinal cord in which the latter shows, anatomically, degeneration of the anterior-horn cells and pyramidal tracts bilaterally, with no evidence of inflammation, compression or vascular disturbance. Clinically, the patient shows weakness, with atrophy of the muscles, usually beginning in the hands, and spasticity, usually beginning in the legs; the two processes relentlessly extend in intensity and in parts involved, and end in bulbar palsy.

Amyotrophic lateral sclerosis in its early stages and even later also simulates a number of other conditions, so that most neurologists advisedly make the diagnosis of "amyotrophic lateral sclerosis syndrome." Later developments show that a large number of these patients do not run the course of the typical Charcot description. Rubenstein<sup>1</sup> has recently emphasized this point: of 8 cases studied, only 4 were typical; the other 4 afforded evidence that somatic disease caused a clinical picture similar to that of the disease under consideration.

The difficulties in diagnosis must be kept constantly in mind before one accepts at face value the results of treatment in these two diseases. And

yet it is fair to say that when the clinical picture is such that either diagnosis has been seriously entertained, the outlook for recovery is not good, and any agent that will arrest the process should therefore be welcome, whatever the exact diagnosis.

In 1939, at the International Neurological Congress at Copenhagen, a paper by Einarson and Ringsted<sup>2</sup> on vitamin E stimulated interest. They observed atrophy and spinal-cord degeneration in rats as a result of vitamin E deficiency. In 1940, Bicknell<sup>3</sup> published a paper reporting such encouraging results in dystrophy that he makes this bold statement, "The discovery of the importance of vitamin E in the treatment of muscular and nervous diseases appears to be revolutionary." He claims improvement in 12 cases of progressive muscular dystrophy out of 13 treated for six weeks or more. Of 4 cases of amyotrophic lateral sclerosis, 2 were improved, and 2 died with bulbar paralysis. His treatment was 15 gm. of dried whole-wheat germ twice daily by mouth. His case reports are meager, frequently only a few lines, and improvement was often admittedly dependent on report rather than personal evidence. On the basis of evidence given, it is difficult for one to reach the optimistic conclusions quoted above. Stone<sup>4</sup> is also encouraged by treatment of pseudohypertrophic muscular dystrophy and of myotonia congenita. Wechsler<sup>5, 6</sup> undoubtedly is chiefly responsible for stimulating interest in vitamin E in the United States. In his later paper, he analyzes 20 of his 30 cases of amyotrophic lateral sclerosis. He admits a difficulty in diagnosis but believes that vitamin E is especially successful in the degenerative type. He used alpha-tocopherol acetate by mouth, up to 50 mg. daily, and intramuscular injections of this drug in oil; he also gave 2 teaspoonfuls of wheat-germ oil by mouth. Vitamin B complex and a vitamin-rich diet were also given. Two patients recovered, 4 showed marked improvement, and 6 improved somewhat.

A number of other papers on this subject have been published during the past year, some strongly in favor, others giving negative results of treatment. Papers written from four large clinics—Cornell, Columbia, Mayo and Harvard—uni-

All articles in this series will be published in book form; the current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

\*Professor of neurology, Harvard Medical School; chief of the Neurological Service, Massachusetts General Hospital.

bilateral frontal trephine openings, the cerebrospinal-fluid pressure being lowered by lumbar puncture to facilitate the filling of the subdural space. An x-ray film showed clearly a tentlike projection of tissue, which prevented air filling in the left postfrontal region. This was subsequently found to be scar tissue and was removed at operation, with cessation of attacks.

It is of course well known that convulsions are a frequent accompaniment of brain tumor. That epilepsy may be the first symptom of tumor is likewise recognized. But it will come as a surprise to many that, in two types of brain tumor,—astrocytoma and meningioma,—seizures occur as the first symptom in 60 per cent and 62 per cent respectively. The figures are from the Montreal Neurological Institute.<sup>21</sup> It is interesting to note that these types of tumor are the two that are most frequently operable; furthermore, the tumors are encapsulated and near the surface of the brain. The obvious deduction from this paper is that a patient with late epilepsy must be considered a "brain-tumor suspect" and every effort made to confirm the diagnosis.

Although uncommon in the United States, cysticercosis as a cause of epilepsy should not be forgotten, particularly in view of the accuracy of diagnosis. The question should always be considered in any patient returning from the Orient. Dixon and Smithers<sup>22</sup> speak of epilepsy, generalized or jacksonian, as frequently occurring in this disease. The brain cysts may or may not be calcified. The diagnosis is made presumptive when large numbers of calcified organisms in the skeletal muscles are revealed either by palpation or by x-ray study.

Ray<sup>23</sup> has recently published a case report of especial interest because of the satisfactory outcome following surgery. The patient evidently became infected in India; the diagnosis was correctly made in 1936 in England on the basis of convulsions and the demonstration of calcified cysticerci in the muscles. Presumably because brain metastasis is often multiple, surgery was not offered at that time. Soon after, Ray successfully removed a solitary cyst from the parietal cortex and confirmed the diagnosis histologically. The patient was said to be well and working, four years after operation.

#### FRONTAL ASSOCIATION AREAS AND OPERATIONS ON THEM

Because the frontal lobes are phylogenetically new and well developed in man as compared with any lower animal species, it is reasonable that they should have been considered the seat of in-

tellect. That this is only partially true is becoming evident, as studies on apes and most significantly on man himself are beginning to reveal. Since operative procedures on this region are now designed with increasing boldness, it is well to consider what is already known.

It is necessary to distinguish the anatomic frontal lobe from the frontal association areas. The posterior portion of the frontal lobe is bound up with motor function, posture, speech and eye movements, and the anterior portion, which is histologically different, has no direct control over these functions. The latter areas, which are so well developed in man, are the regions under consideration: the frontal association areas.

Physiologic evidence of function of these areas, as abstracted from Fulton's<sup>24</sup> work, is as yet not great and not too certain. He states:

The frontal areas are inexcitable to all forms of electrical stimulation and their primary ablation has little if any effect upon reflexes or posture of the extremities in any primate form including man. . . . Unilateral ablation . . . causes no obvious behavioristic disturbance in monkey, chimpanzee or man; but their bilateral destruction leads to a conspicuous syndrome characterized in animals by restlessness, distractibility and failure of immediate memory.

He cites Jacobsen's experiments with apes; these indicate that bilateral ablation appears to show that recently acquired experience could not be assimilated and utilized in problems that were readily solved by the same animals before operation or after unilateral frontal ablation. Jacobsen's experiments with conditioned reflexes were most interesting. When balked, the normal animal became frustrated to a degree approaching neurosis. After bilateral frontal ablation, the same mistakes called forth little or no emotional response. The animal was restless and distractible but presented the "fatuous equanimity of spirit which one encounters in a good-natured drunkard."

Because the frontal association areas are preeminently well developed in man, it is probable that their function will be revealed by studies on man. There is general unanimity of opinion that unilateral ablation or destruction fails to show clinical evidence; neither abnormal performance nor lack of it can be recognized by present methods. Although a tumor of one frontal lobe may be accompanied by personality changes, close analysis invariably discloses the certainty that no abnormality existed until the tumor had expanded sufficiently to implicate the other frontal lobe by pressure or by invasion of the corpus callosum. I have recently had a clear-cut demonstration of this point in a nineteen-year-old girl who at fifteen years of age had had a convulsion. X-ray ex-

amination of the skull at that time showed a definite deposit of calcium in the tip of the right frontal lobe. Since no other symptoms and no further attacks of epilepsy appeared, the patient continued her studies, was admitted to college, and was considered a normal girl in every way. Only when headache supervened five years later, with evidence of increased intracranial pressure, did her intellectual output suffer, together with an alteration of personality of which distractibility, facetiousness and punning were outstanding. At operation, Dr. W. Jason Mixter was obliged to resect the right frontal lobe up to the premotor area because of an invasive tumor, probably an astrocytoma.

Almost every physician will probably recall at least one patient with a small lesion of one frontal lobe, whether from tumor, trauma or abscess, that gave no hint of its presence until sufficiently large to alter the function of both frontal lobes. Jefferson,<sup>25</sup> on the basis of 8 unilateral frontal lobectomies, states: "Those who showed no mental alteration before the operation were unaffected by partial removal of the anatomical frontal lobe . . . those who had mental symptoms [because bilateral function was presumed to be affected] were much better after the lobe had been excised." Nor did Jefferson and other authors find evidence for right or left frontal-lobe dominance if the lesion was confined to the prefrontal region.

In a discussion of frontal-lobe symptoms, bilateral involvement of the frontal association areas is therefore implied. To most observers, the character changes as represented by the general parietic come first to mind; others remember the personality traits of Phineas Gage, whose frontal lobes were largely destroyed by a crowbar.<sup>26</sup> The placard accompanying the skull and bar in the Warren Museum reads, "His disposition was noted to change but in minor ways: he became fitful and vacillating, profane and obstinate, which was different from what he had been before the accident, but no other deviation was noted."

But neither of these examples can safely be depended on as evidence that personality traits reside in the frontal lobes. Nor can one say that the frontal lobes act as a brake on the restlessness, the emotional instability, the joking and the obscenity of such a patient. Brickner<sup>27-29</sup> has made what is probably the first and most extensive study of an appropriate case, a man in whom Dandy removed both frontal association areas because of a tumor (meningioma) confined to this region. The objective characteristics of this man, which continued unchanged from the operation in 1930 to the last report in 1939, were not greatly

different from those of Phineas Gage. The patient was emotionally unstable, a braggart, a wife-baiter and a silly punster, and he was often vulgar and obscene. His mental processes were not deficient, but he showed intellectual inertia. His wife stated that his postoperative traits were not different from what they had been before, but that they were intensified. After thorough psychological tests, Brickner concludes that this array of unproductive traits is the result of a "diminution in the amount of synthesis, which places a limit upon the degree of attainable complexity of thought."

Hebb and Penfield<sup>30</sup> report on bilateral frontal lobectomy in a man presenting post-traumatic epilepsy and a personality change to the extent that he had "become a behavior problem—irresponsible, childish stubborn, restless and forgetful." Following the operation, convulsions were reduced to a minimum, intelligence improved, as shown by specific tests, and behavior was now socially acceptable. The authors are unwilling to commit themselves about the extent to which the frontal association areas influenced the behavior of this man: "It may be that no laboratory study will be adequate to reveal whatever defects follow frontal injury in man because of insufficient control of environmental factors and the difficulty of obtaining a good premorbid rating of ability."

It therefore seems possible to produce certain changes of behavior and disturbance of intellectual balance by partial destruction of the frontal lobes, and also to bring about improvement in behavior and intellect by ablation of the same areas. This brings us to the crucial experiment, usually only possible in the physiologic laboratory, but now practiced on man for therapeutic purposes, that is, bilateral frontal lobotomy on the normal cortex. In this country, Freeman and Watts<sup>31</sup> have been the pioneers in this operation, which consists in cutting the nerve-fiber connections of the frontal association areas: "The white matter in each frontal lobe is cut just anterior to the tip of the ventricle in the plane of the coronal suture." This operation on man may be considered to be based on the observations of Jacobsen on apes, mentioned above, and is used for its stabilizing effect on cases of agitated depression.

Excerpts of three stages of the effects of the operation will give an impression of the results to be expected:

The patients can converse quite rationally during the operation upon either the right or the left side of the brain, but often as soon as the first incision is made in the frontal lobe on the opposite side, there is immediate abolition of anxiety and nervous tension; the pulse and blood pressure fall within a few minutes

the skin of the extremities becomes warm and flushed, and there is considerable sweating. As the incision into the white matter is made more extensive, the patient becomes disoriented, and with the final incision, upward or downward, becomes drowsy or goes into stupor from which he is roused with difficulty and answers in monosyllables.

During the following two or three days or longer, there is vesical incontinence, and the sluggish state persists. Neurologic signs other than these are usually absent. The physical condition remains good. The patients are often restless and try to get out of bed, and upon questioning are found to be completely disoriented. These patients present a placidity and indifference that forms a striking contrast to their previous apprehensive state.

When examination is carried out 7 months after operation, it is found that there is a certain inertia present. The patient responds courteously and accurately, but volunteers little. The relatives state that the patient spends most of his time sitting in a chair, not reading or playing games, apparently perfectly at ease but merely unoccupied. The patients make plans for tomorrow, but somehow, tomorrow never comes. They do enough for today, and then stop. On the other hand, if given a task of more or less repetitive character, they will often continue more or less automatically, beyond the limits of normal patience.

As an antidote to the distressing symptoms presented by a patient who is agitated and depressed, the remote effects of frontal lobotomy as above quoted are very welcome both to the patient and to his relations. The operation restores him to society, but not to competitive occupation. This fortunate outcome has been brought about in a patient known to me whose case was recently reported by Mixer and Tillotson.<sup>32</sup> The patient had remained unchanged for seven years in an institution, but for two years since operation has lived comfortably at home.

There is no clear answer to the question, What is the function of the prefrontal lobes or the frontal association areas? Brickner believes that these areas "synthesize" sensory impressions, Freeman and Watts believe that "they assemble the available data, synthesize them, plan a course of action with the idea in mind, and, equipped with energy of response and with appropriate affective tone, project the individual into the future, direct him toward his goal—and criticize his shortcomings." It also seems probable, as intimated by Hebb and Penfield, that these areas exert a control over psychologic processes that varies with the patient's previous intellectual and emotional life and the social environment in which he lives.

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 27381

#### PRESENTATION OF CASE

A fifty-seven-year-old Italian woman entered the hospital complaining of vomiting of two weeks' duration. Because of the patient's condition, the history was obtained from her husband.

Seven years before admission, the patient visited her physician, complaining of pruritus, weakness and restlessness. A diagnosis of diabetes was made, and she was put on a diet without insulin.

She carried on until six months before admission, when for unstated reasons she saw another physician. He found that the urine contained a large quantity of sugar, boiled solid with albumin, and was full of red cells and casts. At this time, an oculist noted that the fundi showed "a combination of diabetic and albuminuric retinitis." Protamine insulin was now used in doses of 40 units twice a day. Three months later, the patient developed what appeared to be bronchitis, with a chronic cough and white sputum, began to lose weight rather rapidly, and suffered from weakness, headaches, dizziness, dyspnea and ankle edema. The symptoms progressed, and two weeks before admission anorexia and vomiting appeared and she became drowsy and listless. Her physician heard wheezes throughout her chest and recorded a blood pressure of 160 systolic, 90 diastolic. Digitalis was given, but since the vomiting grew worse, it was discontinued.

In the preceding few days, the family had noticed that the patient's speech and behavior were peculiar. At the time of admission, she was nearly blind, had lost 60 pounds in the previous six months, and had complained of frequency and a nocturia of once a night for some time.

At no time had there been pain, orthopnea, hemoptysis, hematuria, gravel, chills, fever, convulsions or localized weakness. Vomiting had ceased five days before entry.

The past and family histories were irrelevant.

On examination, the patient was in no acute distress, but irrational and very unco-operative. The ears, nose and throat were normal; the fundi were not seen. The heart was markedly enlarged

to the left, with a gallop rhythm and an apical systolic murmur; the blood pressure was 210 systolic, 110 diastolic. Moist rales were heard at the lung bases. The liver was palpable two finger-breadths below the costal margin, the abdomen being otherwise normal. Examination of the nervous system was negative, so far as it could be studied.

The temperature was 100.5°F., the pulse 120, and the respirations 25.

The urine ran a specific gravity between 1.008 and 1.015, with a ++++ test for albumin. The blood showed a red-cell count of 4,000,000 with 135 gm. of hemoglobin (photoelectric-cell technic), and a white-cell count of 6500. The nonprotein nitrogen of the blood serum was 38 mg. per 100 cc., the sugar 151, the protein 6.4 gm. per 100 cc.; the chlorides 99.8 and the carbon dioxide combining power 25.9 milliequiv. per liter. The stools were guaiac negative.

An x-ray film of the chest showed the heart to be enlarged in the region of the left ventricle. The lung fields were clear, and the aorta was not remarkable.

With an intravenous pyelogram, the size of the kidneys was in the upper limits of normal. No unusual areas of calcification were seen in the region of the kidneys, but multiple areas of calcification were present in the left side of the pelvis (probably phleboliths). Only traces of dye were visible in the kidney pelves, incompletely outlining them over a course of sixty minutes. Nothing could be said about the shape of the kidney pelves.

The patient was digitalized and given 40 units of protamine insulin daily, the urine remaining sugar free. There was a general improvement for a short time, but she remained disorientated, irrational and sometimes unruly. On the sixth hospital day, the nonprotein nitrogen was 40 and the sugar 140 mg. per 100 cc.; the carbon dioxide combining power was 20.8 milliequiv. per liter. The following day, a flaccid paralysis of the right arm and leg accompanied by aphasia suddenly developed and she was unable to take nourishment. The patient then became comatose, responding only slightly to painful stimuli.

Ten days after admission, tubular breathing and coarse rales were present in the right lower lobe, the temperature rose to 105°F., and the patient vomited occasionally.

Death occurred the next day, the temperature rising terminally to 108°F.

#### DIFFERENTIAL DIAGNOSIS

DR. JOHN H. TALBOTT: This abstract describes the medical history of an Italian housewife who

had suffered from diabetes mellitus for seven years, and from vomiting and mental disorientation for two weeks. The diabetes was presumably mild during the greater part of the period, for no insulin was necessary until six months before admission. The first evidence that something was wrong with the kidneys appeared during a routine examination for urine sugar. It was noted that the specimen boiled solid, probably because of the high albumin content. Examination subsequently revealed red blood cells and casts in the urinary sediment. Examination of the eye grounds showed diabetic and albuminuric retinitis. There is no mention of papilledema of the nerve head, and we can assume that there was not a significant increase in intracranial pressure.

The onset of the present illness may be dated by this examination. The need for 80 units of protamine insulin per day for a patient receiving none previously is significant. I have assumed from this observation that a complication of diabetes mellitus or some new malady was responsible. The story of a weight loss of 60 pounds confirms this assumption. Yet there were no clinical symptoms until three months before entry. The appearance of a chronic cough and white sputum suggested a pulmonary process, and the diagnosis of bronchitis was made. Symptoms of weakness, headache, vertigo, dyspnea and ankle edema then divert our attention from the lungs and center it on the cardiovascular-renal system.

The patient was admitted to the hospital because of vomiting and mental disorientation. I presume we can exclude a brain tumor, because the statement is made in the record that convulsions and localized weakness were looked for but not observed. Furthermore, if an expanding lesion of the brain were responsible for the cerebral symptoms, I should not expect vomiting to cease spontaneously. There is no further information about the eye grounds at the last admission, except that they were not visualized. No mention is made of the flexibility of the neck, and I assume it was not rigid. A gallop rhythm suggests that the heart was functioning at a disadvantage. The apical systolic murmur, enlargement of the heart by x-ray examination and the blood pressure of 210 systolic, 140 diastolic are indicative of further strain on the myocardium.

We have ample evidence of a renal dysfunction. The presence of large amounts of albumin was observed for at least six months. The maximum specific gravity of the urine was 1.015. It is not stated whether the maximum specific gravity was observed during a so-called "urine-

concentration test," or whether this represented the maximum of several casual specimens. Recently, we have been helped by a new test for determining maximum urine specific gravity. The test needs less preparation than the other tests recommended and is probably more accurate. Without previous preparation, the patient is given 0.5 cc. of surgical pituitrin subcutaneously. Half-hourly urine collections are made for three hours, and the volume and specific gravity recorded. A normal person should concentrate to 1.020 during the test.

Turning again to the patient under consideration, it is reported that the nonprotein nitrogen was 38 mg. per 100 cc. and that the serum protein was 6.4 gm. per 100 cc. I believe that the patient was dehydrated on admission, and that this value if corrected for dehydration would be somewhat below normal. The serum chloride, carbon dioxide content and blood sugar were essentially normal. These concentrations do not permit us to make a diagnosis of diabetic acidosis and coma. X-ray studies showed normal lung fields. The intravenous pyelogram showed incomplete outlines of both kidneys, which were at the outer limits of normal in size. No abnormal calcification was seen.

During observation on the ward, the patient was digitalized, with some benefit. Paralysis of the right arm and right leg developed, however, and death followed, with a temperature of 103°F.

In summary, we can say that the patient had diabetes mellitus as well as hypertension. There was hypertrophy of the heart and cardiac decompensation. These diagnoses are given to us in the history.

The matters that we have to decide concern the precise nature of the renal disturbance and the pathogenesis of the cerebral symptoms. With the evidence given, we are entitled to be suspicious of a brain tumor, cerebral abscess, subdural hematoma and tuberculous meningitis. There is not sufficient evidence, however, to implicate any one of these specifically. If we rule out each of these cerebral conditions as being responsible for vomiting, and have no gastrointestinal studies to suggest a peptic ulcer or a neoplasm, it is reasonable to attribute the vomiting to chronic renal insufficiency. The remaining cerebral symptom to be explained, namely hemiplegia, can best be attributed to a vascular accident. Because of the frequent association of hypertension and hemiplegia, I should favor a cerebral hemorrhage.

The renal lesion is even more intriguing. I do not believe that this is a case of the usual variety of acute nephritis, nor am I concerned about the

diagnosis of nephrosis. It is true that most of the clinical findings could be explained by a diagnosis of chronic nephritis, but somehow it does not impress me as being the ordinary variety of chronic nephritis and uremia. This leaves us with but one choice. There is a particular type of kidney lesion observed frequently in patients of this age group suffering from diabetes mellitus and hypertension. The lesion is characteristically confined to the intercapillary spaces. I think it reasonable to believe that this patient had anatomic involvement of the intercapillary spaces, because from 15 to 30 per cent of well-studied autopsied cases of patients with diabetes mellitus and hypertension have such a renal disease.

DR. EARLE M. CHAPMAN: You believe that the lesion shown at autopsy will probably be intercapillary glomerulitis, the type that Kimmelstiel and Wilson<sup>1</sup> reported from the Mallory Institute.

DR. TALBOTT: On the law of probability, I should favor such a diagnosis.

DR. ALLEN G. BRAILEY: Do you not think it is fair to assume that this goes back much longer than six months?

DR. TALBOTT: I doubt if the patient had massive albuminuria for three years.

DR. F. DENNETTE ADAMS: On the ward, we were at first unable to account for the mental picture. When the paralysis developed, we made a diagnosis of cerebral thrombosis rather than hemorrhage, and believed that the mental symptoms could be best explained on the basis of a progressive vascular lesion, which first affected a silent area. We expected that the brain at post mortem would show a large area of infarction.

DR. TALBOTT: It might be of interest to mention the findings of one hypertensive patient examined in this department. The patient had symptoms typical of cerebral hemorrhage, an acute onset of paralysis, and at autopsy no evidence of acute hemorrhage or thrombosis was present. The patient had cerebral disease associated with malignant hypertension but no localized lesion.

#### CLINICAL DIAGNOSES

Diabetes mellitus.  
Hypertension.  
Hypertensive heart disease.  
Nephrosclerosis.  
Cerebral thrombosis.

#### DR. TALBOTT'S DIAGNOSES

Diabetes mellitus.  
Hypertensive heart disease.  
Cardiac decompensation.  
Cerebral hemorrhage.  
Intercapillary glomerulosclerosis.

#### ANATOMICAL DIAGNOSES

Cerebral thrombosis, left internal carotid artery.  
Cerebral infarction, left parietal lobe.  
Intercapillary glomerulosclerosis.  
Cardiac hypertrophy, hypertensive type.  
(Diabetes mellitus.)  
Arteriosclerosis, generalized, severe.

#### PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: At autopsy, this patient showed a thrombosis of the left internal carotid, with an infarct of the left parietal lobe. The heart was hypertrophied, weighing a little over 500 gm. The hypertrophy was for the most part left ventricular, characteristic of the hypertensive type. The kidneys were large, smooth surfaced and somewhat swollen, and at the time of autopsy a definite gross diagnosis could not be made. Microscopically, however, there is no doubt that this is the type of sclerosis within the glomerular tufts that was first described in 1936 by Kimmelstiel and Wilson,<sup>1</sup> the type associated with hypertension, diabetes and very often edema. Practically every tuft shows sclerosis and hyalinization of the connective tissue between the glomerular capillaries. The hyalinization occurs in the central portions of the glomeruli, leaving the peripheral capillaries open.

DR. TALBOTT: Are these cases all associated with diabetes?

DR. CASTLEMAN: I believe so. Recently, the clinical features of this syndrome have been more fully described by Derow and his associates<sup>2</sup> and by Newburger and Peters.<sup>3</sup>

#### CASE 27382

##### PRESENTATION OF CASE

*First Admission.* A fifty-year-old man was admitted to the Medical Service complaining of cough with occasional blood-streaked sputum.

The patient was apparently in good health until seven years before admission, when he developed a severe cold, which confined him to bed for five days and to his home for one week longer. The cold was associated with a severe distressing cough, which caused him to raise occasional blood-streaked sputum. At times, he stated that he had coughed clots of dark-red blood. Following paroxysms of coughing, he occasionally vomited. Fol-

lowing this illness, he noted a persistent wheeze with respiration and a rather constant easy fatigability, malaise and general torpor. During the following six years before admission, he suffered frequent colds, usually in the "chest," which occurred mostly in the winter. With these colds, he experienced difficulty in breathing; he was required to sleep on at least two pillows because lying flat seemed to suffocate him. During this six-year interval, he had also what he described as chronic indigestion and the presence of a vague pain, sometimes sharp, usually associated with coughing and located in the region between the shoulder blades.

Physical examination revealed a thin, wasted, ill-developed man who coughed frequently. There was an acneiform eruption over the back. The teeth were dirty and carious, the chest was slightly asymmetric, and the upper half of the right chest appeared distinctly smaller than the left. There was a slight degree of lateral curvature of the spine. The breathing was described as "rough," and was somewhat prolonged in the expiratory phase. There were coarse musical rales throughout, and a few crepitant rales were audible at the right apex. The diaphragms descended moderately. The right external inguinal ring was slightly dilated. Rectal examination revealed the presence of hemorrhoids.

The temperature, pulse and respirations were normal.

Examination of the urine was negative. Examination of the blood showed a red cell count of 4,600,000 with 80 per cent hemoglobin, and a white cell count of 8600 with 75 per cent polymorphonuclears, 17 lymphocytes, 7 monocytes and 1 eosinophil. The smears were negative. The sputum was negative for acid fast organisms. The stools were guaiac negative. The blood Wassermann reaction was negative. X-ray examination of the chest revealed that the upper part of the right lung field was less radiant than the left. There was a rather dense shadow at the extreme apex. The hilar shadows were increased in size and density on both sides. The larger lung markings were prominent. Both apices were retracted. The patient remained in the hospital for eleven days and throughout the interval in a temperature that ranged from 98 to 99°F, pulse from 65 to 85 and respirations from 20 to 24. He was discharged to a convalescent hospital for chronic supportive care.

*Final Admission* (twelve years later). Since the patient's discharge, he had been in many hospitals for treatment of his chest troubles. He ceased

work two years before admission "because of his heart." One year before entry, he suffered an attack of pneumonia and had been chronically ill since. One month before entry, edema of the ankles appeared, and the dyspnea became severer. It was stated that he was partially digitalized elsewhere at this time. The evening before admission, the patient suddenly became much worse; he noted extreme dyspnea, with coughing, weakness and great malaise. He was referred to this hospital by a local physician.

Physical examination revealed an emaciated man propped up on the shock table and barely able to respond. He was dyspneic, cyanotic and acutely ill, so that the examination was necessarily cursory and brief. The chest was deformed. The respiratory excursions were small and asymmetric. The heart was enlarged, 10.5 cm to the left of the mid-sternal line at the fifth intercostal space. The right border of dullness was located 25 cm. to the right of the mid-sternal line. There was a loud blowing systolic murmur at the apex. The heart sounds were of fair quality. The radial and brachial arteries were moderately thickened, and there was a questionable slight engorgement of the neck veins. The abdomen was slightly distended, and a fluid wave was present. The dependent portions of the abdomen were dull to percussion. There was mild pitting edema of the ankles and sacrum. The scrotum was large.

The temperature was 100°F, the pulse 80, and the respirations 30.

Examination of the blood showed a red cell count of 4,800,000 with 90 per cent hemoglobin, and a white cell count of 28,000 with 82 per cent polymorphonuclears.

On admission, the patient was in extremis. He was dyspneic and semicomatose. He was given morphine sulfate, and a few minutes later the respirations fell to between 7 and 10 per minute. Coramine was given (2 cc intravenously), and the patient responded by talking and joking with his children.

X-ray examination of the chest at this time revealed the heart to be enlarged, without characteristic configuration. There was haziness in the right lower lung field, with questionably dilated bronchi in this area. Several minute areas of marked, increased density scattered through the right mid lung field had the appearance of old lipiodol. The patient was rushed to the ward, and slumped back into a nearly apneic state, with respirations again 7 to 10 per minute. He was placed in an oxygen tent, and given coramine subcutaneously every four hours, and digalen sub-

cutaneously every two hours for three doses. He lapsed into unconsciousness, and died about sixteen hours after admission.

### DIFFERENTIAL DIAGNOSIS

DR. F. DENNETTE ADAMS: The evidence provided by the history at the time of the first admission points toward chronic bronchopulmonary infection—tuberculous or nonspecific. The acute illness that ushered in the trouble may have been pneumonia—the duration of the attack, the severe cough and the bloody sputum are most suggestive. Nonspecific bronchopulmonary infection with bronchiectasis, I believe, can develop after pneumonia or certain other forms of acute respiratory disease. In the presence of this chronic ailment, recurrent episodes of acute bronchopulmonary infection are common, especially during the winter. Fever, cough and respiratory distress, often with the asthmatic form of breathing, characterize such attacks; between them, cough with purulent sputum, occasionally bloody sputum and, perhaps, wheezing respiration are the rule. Pulmonary tuberculosis, obviously, must also be considered, on the evidence provided by the history. Blood-streaked sputum, chronic cough and wheezing, especially if the last is unilateral, when they appear in middle life or beyond should always put one on the alert for bronchiogenic tumor. In this case, the duration of the illness is long for tumor.

The pain associated with coughing is best explained on the basis of a chronic pleuritis. The chronic indigestion seems to be of no importance so far as diagnosis is concerned.

The contraction of the upper half of the right chest and the crepitant rales at the right apex found on physical examination point toward chronic tuberculosis; so does the fact that the man had obviously lost weight. The musical rales, however, are more suggestive of chronic bronchitis or asthma. Nothing in the picture as a whole, however, points toward bronchial asthma as the underlying disturbance.

Failure to find tubercle bacilli in the sputum is of some significance, yet it by no means excludes active tuberculosis. It is rather surprising that the discharge diagnosis did not include at least a question of pulmonary tuberculosis, for there were low-grade fever, even with the patient in bed, bloody sputum, and clinical and roentgenologic evidence of disease at the apices.

With everything taken into consideration, I do not believe a definite diagnosis could have been established at the time of discharge from the first hospital admission.

Twelve years later, nineteen years after the trouble began, an acute episode starting less than a day earlier brought the patient back to the hospital. His symptoms of bronchopulmonary disease had continued, and he had also developed symptoms that were thought to have been related to his heart. More recently, increasing dyspnea and edema of the ankles had appeared.

On physical examination, dyspnea, cyanosis, enlargement of the heart, slight engorgement of the neck veins, ascites and dependent edema were noted—all indicative of right-sided heart failure. The patient also had slight elevation of temperature, definite elevation of respiratory rate and an elevated leukocyte count.

The roentgenologist reported cardiac enlargement and changes in the right lower-lung field. Nothing is stated about the changes previously noted in the upper-lung fields, but it is fair to assume that they were still present. Perhaps only additional changes, compared to those seen in the previous plate, were reported.

We have, then, a man first taken sick with a bronchopulmonary disturbance at the age of fifty, remaining chronically ill with respiratory-tract troubles for nineteen years, and eventually dying of what appears to be right-sided heart failure, with perhaps a terminal acute pulmonary infection. The last named is suggested by the fever and elevated leukocyte count. In my opinion, the problem can be reduced to that of deciding whether the underlying disturbance was tuberculous or nontuberculous. Despite the bloody sputum, the harassing cough and the wheezing, tumor can be excluded by the long course of the disease and the roentgenologic findings. A patient with a bronchiogenic tumor could hardly live this long and still have the diagnosis in doubt. The duration of the illness, the cough, bloody sputum and x-ray findings are consistent with tuberculosis. Yet they are just as consistent with nonspecific bronchopulmonary infection and bronchiectasis. Furthermore, the recurrent attacks of acute infection and the apparent development of right-sided heart failure are strong evidence in favor of the nontuberculous type of disease. It hardly seems likely to me that in the presence of active tuberculosis, the patient could have had so many acute episodes and still recover from them. With tuberculosis of sufficient severity to make him as sick as he was, one of the acute attacks might well have been even more serious or prolonged and resulted in earlier death, or at least after nineteen years one would expect a more characteristic clinical picture of chronic active tuberculosis. Furthermore, in tuberculosis of this duration, x-ray findings should be conclusive.

Taking all these factors into consideration, I am led to the conclusion that the patient died of chronic, nonspecific bronchopulmonary infection, bronchiectasis and cor pulmonale, with right ventricular failure. Acute bronchopneumonia was probably a terminal event. Healed tuberculosis of the apices is likely; the x-ray findings in the upper-lung fields cannot be disregarded.

A PHYSICIAN: Could this possibly be a cerebral embolus to explain the sudden death on this same basis?

DR. ADAMS: Cerebral embolus usually originates in the left auricle in cases of mitral stenosis with or without auricular fibrillation, in chronic auricular fibrillation from other causes, in the left ventricle in cases of coronary occlusion with left ventricular infarction, and in subacute bacterial endocarditis, involving the mitral or aortic valve. None of these were present in this case, nor were there any signs of a cerebral vascular accident.

A PHYSICIAN: Why do you rule out tuberculosis in your diagnosis?

DR. ADAMS: The course of the disease is not typical of tuberculosis, and at the end of nineteen years, changes in the lung more characteristic of progressive tuberculosis should be demonstrable roentgenologically.

#### CLINICAL DIAGNOSES

Bronchiectasis, with pneumonitis.  
Old pulmonary tuberculosis.  
Congestive heart failure.  
Cor pulmonale?

#### DR. ADAMS'S DIAGNOSES

Chronic nonspecific bronchopulmonary infection.  
Bronchiectasis.  
Cor pulmonale.  
Right ventricular failure.  
Terminal acute bronchopneumonia.  
Healed apical tuberculosis?

#### ANATOMICAL DIAGNOSES

Pulmonary emphysema.  
Pulmonary fibrosis, bilateral.  
Bronchiectasis.  
Bronchopneumonia, right lower lobe.  
Septicemia, *Staphylococcus aureus*.  
Cor pulmonale.  
Pulmonary tuberculosis, healed apical, bilateral.  
Arteriosclerosis, moderate cerebral, coronary and aortic.  
Peripheral edema.  
Pleuritis, chronic fibrous.  
Ascites.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: The fundamental process in this case was a chronic, or perhaps more correctly recurrent, pulmonary infection and resultant destruction of the parenchyma of the lungs. At both apices were extensive scars that appeared quite characteristic of healed tuberculosis. There were no foci of activity. Elsewhere, there were extensive fibrosis and emphysema, as well as a diffuse bronchiectasis of many of the smaller radicles of the bronchial tree. It is very improbable that this was due to tuberculosis. There was a terminal acute infection, with spotted foci of early consolidation from which we grew *Staphylococcus aureus*.

The heart was moderately hypertrophied and markedly dilated on the right side, the right auricle being particularly capacious. The right ventricle measured 8 mm. in thickness, which is double the normal value. There can therefore be no doubt of the diagnosis of cor pulmonale. I assume that sudden right-sided heart failure, perhaps precipitated by an infection, was the explanation of the terminal episode. A little qualification is necessary, however, since the coronary arteries showed extensive atheroma, with marked narrowing of their lumens but no points of occlusion. There was enough coronary involvement, however, to make it possible that there was also some left-sided heart failure.

## AMERICAN ACADEMY OF PEDIATRICS

FROM October 8 to 11, the American Academy of Pediatrics will hold its eleventh annual meeting in Boston, with general headquarters at the Hotel Statler.

The membership of the academy, which is the largest pediatric society in the world, is made up of licentiates of the American Board of Pediatrics, and consists of 1400 pediatricians in the United States and Canada. The purpose of the organization—to elevate and maintain standards of practice, teaching, research and public health—is achieved through its annual and regional meetings and through its official organ, the *Journal of Pediatrics*. The academy, with the assistance of local committees and in collaboration with state

medical societies, supports federal, state and local agencies in child health, initiates such work in communities where the need exists, and prepares manuals containing information on immunization, vitamins and health records.

The American Academy of Pediatrics was one of the first medical groups to present subjects by the so-called "round-table method." This year, the program, as noted elsewhere in this issue of the *Journal*, will consist of round-table conferences on allergy, adolescence, feet and shoes, speech defects, orthodontia, adoption and other subjects. In addition to clinics at three Boston hospitals, there will be panel discussions by eminent authorities on vitamin B, intestinal obstruction, and growth and development. Surgeon General Thomas Parran and others will discuss the role of the pediatrician in national defense.

Owing to the large membership and limited seating facilities, the clinics and round-table conferences will be restricted to members of the academy; members of hospital staffs and public-health boards can be admitted without fee to the panel discussions and the scientific exhibits by presenting proper credentials at the registration desk, where guest badges may be obtained. Detailed information can be obtained from Dr. Lewis W. Hill, 319 Longwood Avenue, Boston, chairman of the Committee on Arrangements.

The Massachusetts Medical Society and the *Journal* extend a cordial welcome to the members of the American Academy of Pediatrics.

## THE SCHOOL LUNCH

THE Joint Committee on Health Problems in Education of the National Education Association and the American Medical Association, taking cognizance of the importance of the school lunch, has recently released an official statement concerning this increasingly significant unit in the American dietary.

In adapting the school lunch to the needs of the child, one must recognize and correct the principal nutritional deficiencies most commonly found in American diets. These are calcium, vitamin

B<sub>1</sub> and, in certain areas, iron, iodine and the pellagra-preventive factors, nicotinic acid and riboflavin. Where money is actually lacking for the purchase of food, a deficiency in all the essentials may exist.

Further elaboration is found in the section concerning the food sources from which these deficiencies can be made up: milk for calcium, riboflavin and nicotinic acid; eggs for phosphorus and iron; cheese for calcium and phosphorus, vegetables, fruits and meats for many minerals, including iron; whole grains and the legumes for thiamin; and so forth. Practical elementary advice is given concerning the attractiveness of the diet, economic factors and care in preparation.

The proper and safe feeding of a vast multitude of people, whether in a congested city, in an army or in a nation, constitutes an appalling problem. Not only must a suitable diet be furnished,—and an increasing number of newly discovered factors must be considered,—but the difficulties of transportation and preservation and the economic laws of barter and exchange must be observed.

By and large, in this country, few persons need go hungry or badly nourished. A great deal of education in the selection and preparation of food is necessary, however. We have habituated ourselves to absorbing our calories on the move or at the counter without any loss of time, and with little regard to the balanced diet. A few years ago, at Harvard University, historic, impressive Memorial Hall was forced to close its kitchens and the infinite perspective of its great dining room the students, too impatient to sit, preferred to champ their hamburger rolls with one foot on a rail. If we do not mend our ways and find again the repose that comes from dining, even the Johnsonian\* era will come to an end, replaced by curb service—if the gasoline holds out!

\*H. ward

## MEDICAL EPONYM

### KARELL DIET

Philip J. Karell (1806-1886), physician to His Majesty, the Emperor of Russia, read a paper, "On the Milk Cure," before the Medical Society of

St Petersburg on March 8 and 23, 1865. This was first printed in the *St Petersburg medizinische Zeitschrift* (8: 193-220, 1865). A translation from the author's manuscript by Dr. G. L. Carrick appears in the *Edinburgh Medical Journal* (12, Pt. 1 97-122, 1866), and the essay in *Archives générales de médecine* (8: 513-533, 694-704, 1866). A portion of the translation follows:

After a great deal of experience, I have arrived at the conclusion, that in *all dropsies*, in *asthma*, when the result of emphysema and pulmonary catarrh, in obstinate *neuralgia*, when its cause lies in the intestinal canal, in diseases of the *liver* (simple hypertrophy and fatty degeneration), and generally in diseases where there is faulty nutrition milk is the best and surest of remedies.

I generally commence the cure by employing milk *alone*, and forbidding all *other kinds of nourishment*. I proceed with great caution in prescribing for the patient, three or four times daily, and at *regularly observed intervals*, half a tumbler or a tumbler, *i.e.*, from 2 to 6 ounces, of skimmed milk. During the second week two ordinary quarts are generally administered each day.

R. W. B.

## MASSACHUSETTS MEDICAL SOCIETY

### SECTION OF OBSTETRICS AND GYNECOLOGY\*

#### ALBUMINURIA, FOLLOWED BY FATAL SEPSIS

A thirty-one year-old primipara was sent into the hospital about three weeks before the expected date of confinement because of albuminuria and a systolic blood pressure of 160.

The care during pregnancy had not been entirely satisfactory. The patient had been seen in the third month but probably not again until the seventh month, when nothing abnormal was noted. In the thirty-sixth week, the blood pressure had risen to 150 systolic, 100 diastolic, and a large trace of albumin had appeared in the urine; a good deal of edema was also present. The next week, the blood pressure was 160 systolic, and the patient was sent into the hospital for induction.

Induction of labor was considered because of the albuminuria and hypertension. Labor was induced by the rupture of the membranes, and after ten hours, twins were delivered. The first baby was delivered by low forceps, and the second by version. Three days after delivery, the temperature rose, at the same time, the patient developed a sore throat. She developed phlebitis, a septic

\*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters should be addressed to Dr. Raymond S. Titus, Secretary, 330 Dartmouth Street, Boston.

hip, abscess in the back, many pulmonary infarcts and osteomyelitis of the hip. She was transfused twice. Prontylin was given, but not until the one hundred and twenty-first day of hospitalization. The patient died one hundred and forty-four days after delivery, the temperature vacillating all the time from the third day. Permission for an autopsy was not obtained.

*Comment.* This case represents a type of sepsis that was not infrequently seen years ago. There was no report of blood culture, but such cases are frequently staphylococcal in origin. It is perfectly possible that the infection was induced by the sore throat. It is more probable that the rupture of the membranes and the uterine manipulations of forceps and version were contributory causes. Chemotherapy, applied as it would be today, very early in the onset of this condition might have changed the course of the disease. If the infection had been caused by a streptococcus, it is almost certain that the fatal outcome would have been prevented; if it had been staphylococcal, it is possible that immune transfusions, resorted to early, would have changed the result. Today, any patient who shows signs of infection after delivery should have cultures taken from the throat, blood stream and uterus to determine the specific etiology. After the organism has been identified, intelligent therapy should be instituted immediately. The uterus itself should never be entered. Chemotherapy should be applied in cases in which the organism is one for which the treatment by chemotherapy is known to be valuable. When the infection is staphylococcal, immune transfusions—even though they entail much skilled laboratory work—should be attempted unhesitatingly. All such cases in open wards should be isolated for the protection of other patients. If isolation in puerperal sepsis is not scrupulously followed, epidemics may quickly result. There are about eighty-five deaths each year from puerperal sepsis in Massachusetts. The number should be markedly reduced by the intelligent use of chemotherapy and the intelligent handling of all cases by isolation in maternity hospitals. It must be remembered that even though chemotherapy is invaluable, prevention is more valuable, and that until more adequate supervision is made possible throughout the State,—thereby ensuring clean, gentle operative obstetrics when it is necessary and eliminating much operative obstetrics that would thus be proved unnecessary,—the number of deaths from sepsis will not be materially reduced.

## STATED MEETING OF THE COUNCIL

A stated meeting of the Council will be held in John Ware Hall, Boston Medical Library, 8 Fenway, Boston, on Wednesday, October 1, 1941, at 10:30 o'clock.

### *Business:*

1. Presentation of record of meeting held May 21 and 22, 1941, as published in the *New England Journal of Medicine* for June 26, 1941.
2. Reports of standing and special committees.
3. Appointment of an auditing committee.
4. Fill any vacancies in the offices of the Society.
5. Such other business as may lawfully come before this meeting.

MICHAEL A. TIGHE, *Secretary.*

### IMPORTANT ADDENDA TO BE CONSIDERED BY THE COUNCIL

The Executive Committee will submit the following resolution. The necessity for this resolution has grown out of the confusion which has arisen in the interpretation of certain phraseology contained in Chapter V, Section 2 of the By-Laws of the Massachusetts Medical Society. The resolution, which seeks to have the Council of the Massachusetts Medical Society interpret this language, is as follows:

*Whereas*, the Massachusetts Medical Society is desirous that all skillful and ethical practitioners of medicine in Massachusetts shall be members of the Massachusetts Medical Society;

*Whereas*, Chapter V, Section 2, of the By-Laws of the Massachusetts Medical Society provides the means by which practitioners in medicine in Massachusetts may become members of the Massachusetts Medical Society;

*Whereas*, by the language involved in Chapter V, Section 2, of the By-Laws of the Massachusetts Medical Society the Council of the Massachusetts Medical Society intends that it shall have accurate knowledge of the training, medical skill and ethical conduct of those who seek admission to membership in the Massachusetts Medical Society;

*Whereas*, in the case of graduates of nonapproved schools, Chapter V, Section 2, of the By-Laws of the Massachusetts Medical Society provides that the applicant for membership in the Massachusetts Medical Society shall have been in the practice of medicine for a minimum of five years;

*Whereas*, in establishing such a period of probation for graduates of nonapproved schools, the Council of the Massachusetts Medical Society intends that it shall have had opportunity to closely observe the medical skill and ethical conduct of such applicants;

*Whereas*, in the case of most graduates of foreign medical schools who have been in the practice of medicine for five years in foreign countries, the Council of the Massachusetts Medical Society has no opportunity to know of the training or adequately observe the medical skill and ethical conduct of such medical practitioners; therefore be it

*Resolved*, that the Council of the Massachusetts Medical Society interprets the phrase who has practiced for a minimum of five years, as appearing in the By Laws of the Massachusetts Medical Society, Chapter V, Section (b), to mean what is meant by the phrase, who has fully practiced medicine for a minimum of five years in the United States, be it further

*Resolved*, that the Council of the Massachusetts Medical Society shall be considered to have accurate knowledge of the medical training and medical skill of such graduates foreign medical schools who have practiced medicine in foreign countries for five years and who are eminent in the profession of medicine and well known to the Council of the Massachusetts Medical Society for their scientific attainments, provided such practitioners shall have satisfied the Council of the Massachusetts Medical Society that their medical practice has been ethical according to the standards as set down in the Code of Ethics of the American Medical Association

The Executive Committee will recommend to the Council of the Massachusetts Medical Society that at the annual meeting of the Council of the Massachusetts Medical Society take place on the evening before the annual meeting of the Society, and that the annual meeting of the Society be moved up from the second day of the annual meeting to the first day

It is believed that this does not involve any changes in the By Laws

If this recommendation is adopted, members of the Council will have an opportunity to attend the scientific exercises throughout these sessions. This opportunity has been seriously curtailed under the present setup

The following is submitted by the Special Committee Concerned With Prepayment Medical Care Costs Insurance. This matter comes to the Council as a part of the report of and with approval of the Committee on Public Relations, the Executive Committee has considered this presentation of great length and recommends it to the earnest consideration of the Council. It has to do with tentative set of by laws to govern a corporation (The Massachusetts Medical Service) proposed to be set up under the permissive legislation passed by the current session of the Massachusetts Legislature

## ARTICLE I

### PRINCIPAL OFFICE AND SEAL

*Section 1* The principal business office of the corporation shall be in the City of Boston, County of Suffolk, Commonwealth of Massachusetts.

*Section 2* The seal shall be circular in form with the words Massachusetts Medical Service around the periphery and the words and figures 1941 Massachusetts within

## ARTICLE II

### MEMBERSHIP OF THE CORPORATION

*Section 1* The members of the corporation shall consist of those persons who shall from time to time be the

members of the Executive Committee of the Massachusetts Medical Society

*Section 2* Each member of the corporation shall be entitled to one vote

*Section 3* The annual meeting of the members of the corporation for the choice of directors and the transaction of such other business as shall properly come before the meeting shall be held at the office of the corporation in the City of Boston, or at such other place as may be stated in the call of the meeting, on the last Tuesday of March in each year if not a legal holiday and if a legal holiday then on the next secular day following. In case the annual meeting shall not be duly called and held, the Board of Directors shall call a special meeting in lieu of and for the purpose of such annual meeting and all proceedings at such special meeting shall have the same force and effect as at an annual meeting

*Section 4* Special meetings of the members shall be called by the clerk whenever the Board of Directors or the President shall so order, or upon written request of three or more members, and such request shall state the purpose of such meeting

*Section 5* Notice of the annual meeting and of all special meetings of the members shall be given by the clerk by mailing or delivering to each member at least seven days before the day fixed for the meeting a notice stating the place, day and hour and purpose of the meeting

*Section 6* At every meeting of the members, there shall be represented in person or by proxy at least a majority of the members to constitute a quorum, but a smaller number may adjourn from time to time.

## ARTICLE III

### BOARD OF DIRECTORS

*Section 1* The affairs, property and business of the corporation shall be managed by a board of fifteen directors who may exercise all such powers of the corporation as are not by law or by these by laws required to be otherwise exercised. Directors need not be members of the corporation

A majority of the directors shall at all times be persons approved in writing by the Massachusetts Medical Society. One third of the directors shall be physicians registered to practice medicine in the Commonwealth of Massachusetts and engaged in the active practice of medicine in the Commonwealth, and one third shall be persons who are or who agree to become subscribers to the nonprofit medical service plan to be operated by the corporation

*Section 2* The incorporators at their first meeting shall elect five directors to hold office until the first annual meeting, five to hold office until the second annual meeting, and five to hold office until the third annual meeting. At each annual meeting, the members of the corporation shall elect five directors to hold office for a term of three years and thereafter until their successors are elected, provided, however, that at least thirty days before each annual meeting the members shall submit to the President of the Massachusetts Medical Society a list of those persons whom they propose to elect as directors

*Section 3* Any director may be removed from office by a majority of the members of the corporation either by writing filed with the clerk of the corporation or by a vote passed at a meeting of the said members

*Section 4* Vacancies in the Board of Directors occurring during the year shall be filled by a majority vote of those members present at a meeting duly called for such

purpose, provided, however, that at least thirty days prior thereto the members shall submit to the President of the Massachusetts Medical Society the name of the person they propose to elect as a director.

*Section 5.* A majority of the directors in office for the time being shall constitute a quorum for the transaction of business, but a smaller number may adjourn from time to time.

*Section 6.* Regular meetings of the directors shall be held immediately after the adjournment of the annual meeting of the members of the corporation at the place of holding the annual meeting and at such times and places as the Board of Directors may determine and no notice of such meetings shall be necessary. Special meetings may be held in like manner and shall be called by the clerk whenever the President or any three directors shall so request in writing, and three days' notice of such meetings shall be given to each director not joining in the request for such meetings unless shorter notice shall be reasonable in the circumstances. Any meeting of the Board of Directors shall be a legal meeting without notice if each director, by a writing filed with the record of the meeting, waives such notice.

*Section 7.* The Board of Directors shall have power to purchase any property or rights and to enter into any contracts which they deem advantageous to the corporation, to fix the price to be paid by the corporation for such property, rights or contracts, to borrow money, to issue bonds, debentures or other securities of the corporation and pledge or sell the same for such sums and at such prices as they may deem expedient, to adopt rules and regulations subject to the provisions of Article IV hereof and in general to exercise such other powers and to do all such other things as are not required by any other article of the by-laws to be exercised or done by any committee named therein.

No contract or other transaction between this corporation and any other corporation shall in any way be affected or invalidated by the fact that any of the directors of this corporation are pecuniarily or otherwise interested in or are directors of such other corporations and any director of this corporation may be a party to and may be pecuniarily or otherwise interested in any contract or transaction of this corporation provided that the fact that he is so interested shall be disclosed or shall be known to the Board of Directors or a majority thereof and his vote shall not be necessary to authorize or ratify any such contract or transaction.

*Section 8.* Directors as such shall not receive any stated salary for their services, but by resolution of the board a fixed sum and expenses of attendance, if any, may be allowed for attendance at board meetings. Nothing herein contained shall be construed to preclude a director from serving the corporation in any other capacity and receiving remuneration for such service.

*Section 9.* The Board of Directors may from time to time delegate any of its powers to committees or officers, attorneys or agents of the corporation subject to such regulations as may be adopted by the board.

## ARTICLE IV

### COMMITTEES

*Section 1.* The directors may appoint such committees as they deem necessary, including an Administrative Committee and a Finance Committee, and they shall appoint a Central Professional Committee and an Actuarial Research Committee as provided herein.

*Section 2.* There shall be a Central Professional Service Committee composed of five directors appointed by the president of the corporation, of whom four including the chairman shall be physicians registered to practice in the Commonwealth of Massachusetts. The chairman of the Committee shall be designated by the president of the corporation.

*Section 3.* The Central Professional Service Committee shall have delegated to it control and supervision of the medical aspects of all matters relating to (a) the standards of medical care to be furnished subscribers, (b) the qualifications of specialists, (c) the extent and classification of medical benefits to be furnished subscribers, (d) the determination of income groups eligible to become subscribers, (e) the compensation to be paid participating physicians, and (f) the admission, suspension and discipline of participating physicians. All rules and regulations of the corporation relating to the foregoing shall be initiated by the Central Professional Service Committee, provided, however, that any rule or regulation relating to the determination of income groups eligible to become subscribers shall first be approved by the Council of the Massachusetts Medical Society. Whenever the committee shall initiate any change in a rule or regulation, it shall give at least thirty days' notice thereof to the President of the Massachusetts Medical Society.

*Section 4.* In the event of a complaint relative to the conduct or services of a participating physician or of any controversy between a participating physician and a subscriber or whenever it has reason to believe that a participating physician has been guilty of a violation of the rules and regulations of the corporation, or unprofessional or unethical conduct or of conduct which is liable to endanger the interests of the corporation or of any of its subscribers, the committee shall refer the matter for investigation to the District Professional Service Committee within whose district the physician concerned has his principal office, which shall investigate the matter and shall then report the result of its investigation to the Central Professional Service Committee. If it appears to the Central Professional Service Committee that there is reasonable cause to believe that the participating physician has been guilty of a violation of the rules and regulations of the corporation, of unprofessional or unethical conduct, or of conduct which is liable to endanger the interests of the corporation or of any of its subscribers, it shall assign a date for a hearing giving the participating physician concerned at least seven days' notice thereof. If at the hearing, at which the participating physician shall be given full opportunity to be heard, the said committee shall find the said physician guilty, it shall terminate the agreement between the said physician and the corporation, or it may take any other disciplinary action which is proper and appropriate in the circumstances, having first, however, reported to the President of the Massachusetts Medical Society its findings and having obtained his approval of its proposed action.

*Section 5.* The Central Professional Service Committee shall report its acts and proceedings to the Board of Directors at such times as the Board of Directors shall require.

*Section 6.* There shall be an Actuarial Research Committee of at least three directors appointed by the president of the corporation who shall designate one of the members as chairman.

*Section 7.* The Actuarial Research Committee shall obtain actuarial data as to incidence of demand for medical services and the cost thereof, shall analyze the data and

and report to the Board of Directors hereon. It shall have the power, subject to the approval of the Board of Directors, to engage such persons to assist in this work as it may deem necessary.

## ARTICLE V

### OFFICERS

*Section 1* The officers of the corporation shall be a president, a treasurer, a clerk and such subordinate officers as the Board of Directors shall from time to time appoint with such powers and duties and for such terms of office as the directors may designate. The president shall be chosen from among the directors of the corporation; no other officers need not be. The directors at their annual meeting in each year shall elect the aforesaid officers, provided, however, that the incorporators at their first meeting shall elect a treasurer and clerk to hold office until the first annual meeting. All of the said officers shall hold their respective offices for one year and thereafter until their successors are elected and qualified, subject, however, to removal at any time by vote of a majority of the Board of Directors, except that the officers appointed at the first meeting of the Board of Directors shall hold office only until the first annual meeting and thereafter until their successors are elected and qualified. Vacancies in any of the said offices shall be filled for the unexpired portion of the term by the Board of Directors. Officers may be paid such salary or compensation as the Board of Directors shall determine.

*Section 2* The president shall be the chief executive officer of the corporation. He shall preside at all meetings of the Board of Directors. He shall see that all orders and resolutions of the Board of Directors are complied with.

*Section 3* The treasurer shall have charge of the corporation's financial affairs, subject however to the supervision and control of the Board of Directors. He shall have the custody of all money and securities except his own bond, which shall be kept by the president. He shall deposit all money and valuables in the name and to the credit of the corporation in such depositories as shall be determined by the Board of Directors. He shall disburse the funds of the corporation as ordered by the Board of Directors. He shall keep or cause to be kept the corporation's accounts in suitable books wherein every transaction shall be accurately recorded and shall render to the president and directors at regular meetings of the board whenever they require it an account of his transactions as treasurer and of the financial condition of the company and shall discharge all other duties properly appertaining to his office or which may be attached thereto by the Board of Directors. He shall give bond for the faithful discharge of his duties in such form and in such sum as the Board of Directors may require.

*Section 4* The clerk shall keep the records of all meetings of the members and of the Board of Directors and shall give notice of all meetings required by these bylaws. He shall have the custody of the record books of the corporation and shall perform all duties usually incident to the office of clerk and such other duties as may be from time to time assigned to him by the Board of Directors.

## ARTICLE VI

### DISTRICT COMMITTEES

*Section 1* Each district medical society in the Commonwealth may appoint a District Administrative Unit composed of not more than nine members of whom a

majority shall be physicians engaged in active practice within the district and shall designate one of the members of the committee who is a physician as chairman.

*Section 2* Each District Administrative Unit shall assist in the operation of the medical service plan and in obtaining subscribers thereto within its district and shall perform such duties as the Board of Directors may prescribe. It shall from time to time make recommendations to the Board of Directors as to any phase of the operation of the medical service plan except one within the jurisdiction of the District Professional Service Committee.

*Section 3* Each district medical society may appoint a District Professional Service Committee, composed of at least five physicians engaged in active practice within the district and shall designate one member thereof as chairman.

*Section 4* Each District Professional Service Committee shall act in co-operation with and under the supervision of the Central Professional Service Committee. It shall from time to time survey the quality of medical care rendered to subscribers within its district and shall report thereon to the Central Professional Service Committee. It may report to the Central Professional Service Committee on the qualifications of specialists within its district and may compile and from time to time revise, under the supervision of the Central Professional Service Committee, a list of specialists within its district according to the accepted policy of the Massachusetts Medical Society, which may be used for the benefit of subscribers to the medical service plan. It shall make recommendations to the Central Professional Service Committee as to all matters within its jurisdiction.

*Section 5* Each District Professional Service Committee shall, whenever any matter relating to the services or conduct of a participating physician or relating to a controversy between a participating physician and a subscriber is called to its attention by complaint or otherwise, fully investigate the matter and report hereon to the Central Professional Service Committee.

## ARTICLE VII

### SUBSCRIBERS

*Section 1* A resident of the Commonwealth may become an unlimited subscriber to the medical service plan provided that his annual income does not exceed such amount as shall be fixed by the Board of Directors as provided in Article III, Section 7, and provided further that he make application to become a subscriber as one of such a group as the Board of Directors may specify.

*Section 2* An unlimited subscriber shall be entitled to receive from a participating physician such medical services as are included in the subscriber's contract with the corporation, subject to whatever rules and regulations may be adopted by the Board of Directors relative thereto.

*Section 3* A resident of the Commonwealth may become a limited subscriber to the medical service plan if his annual income exceeds such amount as shall be fixed by the Board of Directors on such terms and conditions as the Board of Directors may by regulations prescribe.

*Section 4* A limited subscriber shall be entitled only to such benefits as are provided in his contract with the corporation. The corporation shall have no supervision over the amount to be charged by a participating physician for services to a limited subscriber.

*Section 5* Subscribers shall have free choice among participating physicians subject to the provisions of Article

VIII, Section 3 hereof, and to the rules and regulations adopted by the Board of Directors.

*Section 6.* The Board of Directors shall have power to enter into arrangements and agreements with employers, societies, charitable organizations, and governmental agencies and authorities for the payment of part or all of the cost of medical care furnished to any persons who may be entitled to such care under the rules and regulations adopted by the Board of Directors.

## ARTICLE VIII

### PARTICIPATING PHYSICIANS

*Section 1.* Any physician registered to practice in the Commonwealth may become a participating physician on complying with the provisions of these by-laws and the rules and regulations of the corporation.

*Section 2.* A physician desiring to become a participating physician shall make written application in the form prescribed by the rules and regulations and shall before becoming entitled to act as a participating physician enter into a written agreement with the corporation in the form prescribed by the rules and regulations.

*Section 3.* A participating physician shall have the right to accept or reject patients so far as subscribers are concerned and the right to discontinue treatment of any subscriber according to the code of ethics of the American Medical Association, provided, however, he shall not have the right to refuse to accept a subscriber as a patient or to continue treatment of a subscriber for the sole reason that he is a subscriber and such refusal shall constitute grounds for the termination by the corporation of its agreement with a participating physician.

*Section 4.* A participating physician shall not request or accept from anyone whom he knows to be an unlimited subscriber any compensation for such services as such subscriber is entitled to under his contract with the corporation, except such initial service charge, if any, as may be required by the rules and regulations adopted by the Board of Directors.

## ARTICLE IX

### AMENDMENT OF BY-LAWS

*Section 1.* These by-laws may be amended or repealed by vote of the majority of the members of the corporation.

## MISCELLANY

### RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR JULY, 1941

DISEASES	JULY 1941	JULY 1940	FIVE YEAR AVERAGE*
Anterior poliomyelitis	5	3	9
Chicken pox	519	384	380
Diphtheria	9	7	18
Dog bite	1336	1353	1211
Dysentery, bacillary	26	97	25
German measles	116	30	53
Gonorrhea	344	335	426
Lobar pneumonia	155	183	175
Measles	1420	2830	1331
Meningitis, meningococcal	5	0	3
Meningitis, other forms	8	—	—
Mumps	534	358	313
Paratyphoid fever	4	12	10
Scarlet fever	232	196	240
Syphilis	388	424	442
Tuberculosis, pulmonary	224	255	306
Tuberculosis, other forms	31	18	30
Typhoid fever	5	3	15
Undulant fever	4	4	4
Whooping cough	659	521	520

\*Based on figures for preceding five years

### GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: New Bedford, 3; Quincy, 2; total, 5.

Diphtheria was reported from: Arlington, 1; Boston, 2; Fall River, 3; Gloucester, 1; Somerville, 1; Taunton, 1; total, 9.

Dysentery, bacillary, was reported from: Arlington, 2; Boston, 1; Salem, 1; Waltham, 9; Worcester, 12; Wrentham, 1; total, 26.

Infectious encephalitis was reported from: Waltham, 1, total, 1.

Meningitis, meningococcal, was reported from: Boston, 1; Camp Edwards, 1; Everett, 1; Milford, 1; Palmer, 1; total, 5.

Meningitis, other forms, was reported from: Arlington, 1; Chicopee, 1; Haverhill, 1; Lawrence, 1; Palmer, 1; Quincy, 1; Springfield, 1; Worcester, 1; total, 8.

Paratyphoid fever was reported from: Beverly, 1; Boston, 1; Haverhill, 1; Saugus, 1; total, 4.

Pellagra was reported from: Boston, 1; Wakefield, 1; total, 2.

Septic sore throat was reported from: Arlington, 1; Boston, 3; Brockton, 1; Easton, 1; Somerville, 1; Waltham, 1; total, 8.

Tetanus was reported from: Quincy, 1; total, 1.

Trachoma was reported from: Boston, 1; New Bedford, 1; total, 2.

Typhoid fever was reported from: Boston, 1; Brockton, 1; Dennis, 1; Haverhill, 1; Middleboro, 1; total, 5.

Undulant fever was reported from: Leominster, 1; Westboro, 1; West Brookfield, 1; Whitman, 1; total, 4.

Chicken pox, German measles, mumps and whooping cough showed the usual seasonal decline but were reported above the five-year averages.

Meningitis, both meningococcal and other forms, continued above normal levels.

Dog bite, bacillary dysentery, measles, scarlet fever and undulant fever were at about the expected prevalence for the season.

Anterior poliomyelitis, diphtheria, gonorrhea, lobar pneumonia, paratyphoid fever, syphilis, pulmonary tuberculosis and typhoid fever were less prevalent than usual.

## BOOK REVIEWS

*Chest X-Ray Interpretation, with Special Reference to Tuberculosis.* By J. Burns Amberson, Jr., M.D. 8<sup>th</sup>, 2<sup>nd</sup> ed., 48 pp., with 30 illustrations. New York: National Tuberculosis Association, 1941. 25 cents.

This small brochure is a short discussion and a description of the commoner x-ray findings in pulmonary tuberculosis. The author has had many years of experience in both diagnosis and treatment of pulmonary tuberculosis. In addition, because of his many years as a student of tuberculosis, he is well qualified for this work.

The book includes an excellent discussion of the technical aspects of x-ray examinations, as well as an intelligent and judicious consideration of the pathogenesis and evolution of tuberculosis, indications for x-ray examinations of the chest, and roentgenographic appearances and interpretations of tuberculous lesions. With the greater popularity of the x-ray apparatus as the standard part of the internist's and the general practitioner's office equipment, intelligent guidance in this subject is indeed welcome. The busy practitioner will find a good deal of common sense as well as sound scientific material clearly written.

and well illustrated Dr William C Cutter in his foreword cautions, however, against too much self reliance by the internists and points out the necessity of expert radiologic consultation, which is still a factor of the medical service.

The National Tuberculosis Association has previously published many authoritative small volumes on different phases of tuberculosis. This brochure is an excellent addition to this fine series of publications and should be read by all interested in the subject of pulmonary tuberculosis.

*Emergency Surgery* By Hamilton Bailey, FRCS Fourth edition 8°, cloth, 944 pp., with 930 illustrations. Baltimore: Williams and Wilkins Company, 1940 \$10.00

In reading this book, one is struck by the diversity of material presented, for it includes all phases of emergency surgery in various parts of the body. It is to be remembered that in England specialization is far behind the practice of metropolitan America. Over there, a general surgeon is such in fact and can be summoned to deal with any surgical condition by a fellow practitioner. This book represents the wealth of experience accumulated by the more successful surgeon under such a system.

This is the sort of meaty volume that a general surgeon in the smaller hospital enjoys. It solves many of his practical problems, while introducing a minimum of the theory that only confuses a busy practitioner. But this feature also adds an element of weakness, in that some well-established procedures of recent origin are not considered in detail. The Miller-Abbott tube is described but its use is not specifically recommended in the treatment of the paralytic ileus that so often accompanies peritonitis. Cecostomy and ileostomy, however, are recommended as useful measures in this condition. In discussing the administration of parenteral fluids over a period of days, the author notes the threat of edema but he does not counsel the use of distilled water and glucose in proper amounts to offset the positive balance of sodium chloride.

One of the outstanding features of the editorial policy used by the author is the case history. This has been largely abandoned in modern textbooks in which the statistical method is presented. However, the case history defines the specific problem far better than a group of figures, and in this book it is used with good effect.

This volume and the book on war surgery edited by the same author are two works that will be appreciated by all who deal with surgical emergencies.

*Age Morphology of Primary Tubercles* By Henry C Sweeney, MD 8°, cloth, 265 pp., with 73 illustrations. Springfield, Illinois: Charles C Thomas, 1941 \$5.00

This book describes an interesting and extensive clinicopathological investigation of the primary type of tuberculous infection in man. In his studies, the author found a rather remarkable similarity of structure in tubercles of the same approximate age. He also found a definite sequence of changes in all tubercles with respect to maturation, degeneration, regeneration and metaplasia.

In this interesting and novel study, both from pathologic specimens and from thorough x-ray examinations, he concludes that about 90 per cent of the primary infections in which the calcified residues persist may be given an age rating by pathological methods that are accurate within plus or minus 25 per cent in lesions between six months

and twenty years of age. The age determination of the tubercle by pathological methods was followed on many contacts and on many selected cases to determine the potential relation of tuberculosis to attacks of pleurisy and pneumonia and to occupations, such as the nursing of tuberculous patients. In most studies, the results were, according to the author, surprisingly accurate. In life, however, this study was found to have little importance, because he found that only about 20 per cent of such primary tuberculous infections are visualized on the x-ray film. He also noted what most of us were taught previously: any lesion that is large and not well calcified is potentially dangerous. In addition, the soft lesions are dangerous.

In a series of cases that were kept under control, such as those of nurses and hospital attendants, the author traced the tuberculous infection to the period of contact at the hospital or sanatorium and obtained certain constant morphologic changes. Thus, he believes that in such cases the method might be applied in determining the liability as well as the probable source of the infection. In addition, he employed this method with some success in studying the reinfectious type, especially when repeated tuberculous infection had been spaced over a period of years. The book offers very interesting and intriguing material for the pathologist and should stimulate as well as help the research worker in the field of tuberculosis. However, the facts that ante-mortem x-ray films reveal only 20 per cent of primary lesions, of which only part reveal any age changes, and that most of them demonstrate no changes after eight years are rather discouraging to the clinicians.

The volume should make a very valuable addition to the library of men engaged in tuberculosis work.

*Help Your Doctor to Help You When You Have Sick Headache or Migraine* Edited by Walter C Alvarez editor in chief, George Blumer, Logan Clendening, Irving Cutter, Howard W Haggard, Rudolph Matas, Charles W Mayo, George R Minot, John H Stokes and George H Whipple 8°, cloth, 37 pp. New York: Harper and Brothers, 1941 95 cents

An editorial board of ten distinguished physicians is sponsoring a series of booklets, each dealing with a common complaint. The authorship of these booklets is anonymous, but internal evidence points to the gastroenterology department of the Mayo Clinic as the probable birthplace of the booklet on migraine. Obviously, the writer is an authority on the subject and presents his points of view clearly and forcefully. The only criticism of the medical treatment of the subject is the almost exclusive emphasis on psychic (emotional) factors, and warnings against mistreatment of the brain, whatever that means.

Efforts to educate patients to co-operate intelligently with their physicians are laudable. The task of supplementing without supplanting the individualized advice of the patient's physician is not easy, and in this respect the author of the booklet speaks like a professor of medicine, directly advising the patient, and not like a self-effacing, diplomatic assistant to the patient's physician. He disparages the efforts of the physician by repeated examinations to discover contributing causes of the headaches and to correct physical abnormalities, which have no proved influence in all cases of migraine. Apparently, the patient puts himself on an elimination diet and selects a headache reliever. Only once was the reviewer able to

## UNITED STATES NAVAL HOSPITAL

The dates, subjects, and speakers for the 1941-1942 medical meetings at the United States Naval Hospital in Chelsea are listed below. The meetings are scheduled to begin at 8:15 p.m., and are open to those who are interested.

October 10—The Nature and Treatment of Organic Arterial Disease. Dr. Edward Edwards.

November 14—The Modern Treatment of Pneumonia. Dr. Maxwell Finland.

December 1—The Management of Hand Injuries and Infections. Dr. Henry Marble.

January 9—Blood Transfusions. Dr. Francis T. Hunter.

February 13—Head Injuries. Dr. Donald Munro.

March 13—Evaluation of Surgical Risk from a Cardiovascular Viewpoint. Dr. Samuel A. Levine.

April 10—The Relation between Renal Infection and Hypertension. Dr. Soma Weiss.

SEVENTH POSTGRADUATE SEMINAR  
IN NEUROPSYCHIATRY

The Metropolitan State Hospital, Waltham, recently announced the opening of the Seventh Postgraduate Seminar in Neuropsychiatry.

The course consists of three units: military neuropsychiatry, October 3 to 31; general psychiatry, November 3 to December 12; and general neurology, January 5 to April 10. It is open to a limited number of graduate physicians. The teaching staff comprises a number of recognized specialists in this field throughout the state, and is under the direction of Dr. Roy D. Halloran, superintendent, Metropolitan State Hospital, and Dr. Paul I. Yakovlev, clinical director, Walter E. Fernald State School.

## FRACTURES OF THE FOREARM AND ELBOW IN CHILDREN\*

An Analysis of Three Hundred and Sixty-Four Consecutive Cases

AUGUSTUS THORNDIKE, JR., M.D.,† AND CHARLES L. DIMMICK, JR., M.D.‡

BOSTON

IN making a study of children's fractures, one cannot but realize that growing bone, epiphyses and the extraordinary power of repair are major factors to be considered. However, there is no reason because of this reparative power that the surgeon or medical man treating these cases should be satisfied with a poor anatomic reduction. One often hears it said that if half the surface of a fractured bone fragment is in apposition, Nature will produce a satisfactory result. With the growing demand of the public for better medical and surgical care, it behooves physicians to be satisfied only with the product of their very best effort. Today, there should be no half way measures in fracture therapy.

The subject of this communication covers an important region of the child's body, a region involved most commonly in fractures. Beekman and Sullivan<sup>1</sup> report, in a series of over 2000 fractures in children, that 75 per cent were in the long bones of the upper extremity and that the radius was the most frequently fractured long bone in the body. The clavicle has usually been considered to be commonly injured, but it represented less than 8 per cent in their series. Figures will doubtless vary in different age groups of children, the clavicle being certainly the most commonly fractured bone at birth.<sup>2</sup> However, this paper is concerned with the age group from one day to twelve years.

During the last three and a half years, 364 consecutive cases of fracture of the forearm or elbow have been treated at the Children's Hospital. Of

these, the distal third of the forearm was involved in 200 cases, the middle and proximal thirds of the forearm in 58, and the elbow, including the head and neck of the radius and olecranon, in 106. From this series, dislocations of the distal radial epiphysis are omitted, being more properly included in wrist rather than forearm fractures.

In the treatment of fractures in the growing child, one should always be guarded in giving a prognosis, particularly when injuries to the epiphyses are involved. Aitken<sup>3</sup> has analyzed these fractures and has drawn some good conclusions. Abbott<sup>4</sup> has ascertained by a practical arithmetic formula the expected growth of a shaft attached to a damaged epiphysis. To interfere with normal growth, the fracture must pass through the cartilage plate and injure the proliferating cells. Separation of an epiphysis does not ordinarily injure these cells.

### FRACTURES OF DISTAL THIRD OF FOREARM

The character of bone in the growing child is such that a long bone fracture is often incomplete. In this series of 200 cases of fracture of the distal third of the forearm, 102 (51 per cent) had incomplete fractures, either subperiosteal or true greenstick in character, of 58 cases with fracture of the middle or upper third of the shaft of the forearm, 16 (28 per cent) had incomplete fractures, and of 106 cases with elbow fractures, 23 (22 per cent) had incomplete fractures. Thus, it appears that the more distal the fracture of the forearm, the greater is the likelihood of an incomplete fracture.

The treatment of these incomplete fractures is aimed at restoring proper anatomic alignment. A simple subperiosteal crack or impaction where the alignment remains normal needs no manipulative correction, merely fixation. The greenstick

\*Presented at the annual meeting of the New Hampshire Medical Society, May 13, 1941.

‡Associate in surgery, Harvard Medical School; associate surgeon, Children's Hospital.

§Associate in surgery, Harvard Medical School; resident in surgery, Children's Hospital.

shaft fracture with angulation requires manipulation, and often sufficient force to break the shaft completely through, to attain alignment, before fixation is applied. There are exceptions, however, even to this—notably greenstick fractures of the clavicle.

The necessity for surgical intervention in the treatment of fractures in this region should be determined by judgment acquired by experience. Beekman and Sullivan,<sup>1</sup> Whipple and St. John,<sup>5</sup> Ashurst<sup>6</sup> and Bosworth<sup>7</sup> agree that open reduction is rarely indicated. However, when necessary, it should be performed within forty-eight hours of the failure of closed reduction, with meticulous aseptic technic and with a minimum of trauma. At the Children's Hospital, we have never resorted to the use of bone plates, screws or other forms of advertised hardware; a reposition of fragments and periosteal suture, and occasionally wire suture, are employed. In only 2 (1 per cent) of the cases with fracture of the distal third of the forearm, six weeks and three weeks old, respectively, was open reduction necessary.

The art and science of closed manipulative reduction followed by proper fixation seem to be fast disappearing from the present era of surgical development. Admittedly, not all fractures can be adequately reduced by closed reduction, but the temptation to obtain anatomic alignment by open reduction is great in this age of gadgets. The aim of treatment is perfect function and as nearly as possible anatomic realignment and continuity. However, malunion and nonunion require all that surgical skill can provide—a different phase of fracture therapy. Compound fractures require careful débridement and surgical care. As yet, we have not adopted the Orr<sup>8</sup> or Trueta<sup>9</sup> method and can report that our 2 cases of compound fracture in this series (both in the distal third of the radius) healed by primary union.

The treatment that we recommend consists in early closed reduction, followed by adequate fixation. In fractures of the distal third of the forearm, not a Colles in children, some resort to the fluoroscope as an aid, but the cautious technician uses this piece of apparatus very seldom. Digital palpation and observation should assist one in ascertaining the proper alignment, and fixation should be promptly applied. X-ray films must be taken promptly after reduction and the application of fixation, not only to satisfy the surgeon of his manipulation, but also to serve as a safeguard against possible future litigation. Fixation is usually applied with molded plaster splints with the hand in semipronation; the plaster is carried around the elbow in true "sugar-tongs" fashion if it is

believed that the mobility of the upper fragments should be limited (Fig. 1).<sup>\*</sup> Board splints are still used, and give excellent results when properly applied.

When these patients are ambulatory in a sling,

FIGURE 1. Fractures of the Distal Third of the Forearm Treated with a Molded Plaster Splint.

A cylinder is used in A, and a typical "sugar tong" in B.

one should follow them at least twice a week, removing and repadding and adjusting the splints at regular intervals. The posterior splint should be removed after three weeks, the anterior splint after four weeks, and the sling after six weeks.

TABLE 1. Results of Treatment in Fractures of the Distal Third of the Forearm.

In our series, there were 9 cases of refracture between one month and five years following the original injury.

Table 1 presents the results of treatment in fractures of the distal third of the forearm.

#### FRACTURES OF PROXIMAL TWO THIRDS OF FOREARM

In fractures of the proximal two thirds of the bone shafts of the forearm, early reduction and

<sup>\*</sup>Surgeons experienced in the use of the more recently developed plastic materials (Castex and Thermex) may substitute these light waterproof molded splints for plaster of Paris.

adequate fixation are essential. Careful closed manipulation, with fluoroscopy as an aid, must be promptly carried out. In this portion of the forearm, palpation is less accurate, and x-ray visualization is of value. Whipple and St. John<sup>5</sup> have

FIGURE 2. The Use of a Plaster-Bandage Roll, over the Flexor Surface of the Forearm, as an Extra Aid to Fixation in Fractures of the Proximal Two Thirds of the Forearm

recommended full supination of the hand as the position for fixation, with the elbow flexed to 90°, and an internal angular splint of metal. Plaster of Paris is now the customary splinting material, and is put on as a full cylinder from the knuckles

FIGURE 3. The Use of Internal Angular and Board Splints for Immobilization of Fractures of the Proximal Third of the Forearm.

Supination rather than the neutral position may be substituted.

to the axilla, with the hand in supination and the elbow in extension or in right-angle flexion (Figs. 2 and 3). It is impossible to set any hard and fast rule for the latter, because no two cases are exactly alike and each is an individual problem.

Flexion will hold some, but not all. The use of a narrow roll of plaster bandage placed between the layers of plaster on the flexor surface of the supinated forearm in the area of the interosseous membrane does assist in holding these bones in alignment. A sling is used when the elbow is fixed at 90° flexion.

It is best to leave the original plaster for three or four weeks and then secure partial immobilization in molded plaster splints for another two or three weeks. Beekman and Sullivan<sup>1</sup> recommend fixation for eight weeks, because of the apparent likelihood of refracture. Although this period seems long to us, it is safe, but will not prevent all refractures. Our series of 58 patients

with fractures of the upper two thirds of the forearm includes one with refractures at the original site three times in three years, 2 cases with refracture in two years, and 4 cases with refracture between three months and thirty-three months after the original injury. Of this entire group, not one case required open reduction. On the whole, the results of this method of treatment are entirely satisfactory (Table 2).

#### FRACTURES OF ELBOW

In fractures of the elbow, particularly those of the distal end of the humerus, one should follow the principles set down by Ashurst<sup>6</sup> in 1910 and emphasized again by Ladd<sup>10</sup> in 1916. The results are surprisingly good with conservative treatment, although one should remember that if premonitory signs and symptoms of Volkmann's ischemic contracture appear within the first twenty-four hours, the fracture should be "taken down," the skin prepared, and open reduction and evacuation of the hematoma performed within forty-eight hours. In all types of fractures, Ashurst with 56 cases had 81 per cent "perfect" results, and Ladd with 45 cases had 91 per cent. In the purely supracondylar and transcondylar types, their results are even better. The problem comes down to a definition of the adjective "perfect." We consider that perfect function entails no greater total loss of

combined flexion and extension than  $10^{\circ}$  (a maximum limitation of  $5^{\circ}$  each), with normal supination and pronation and a carrying angle with a cubitus varus or valgus of only slight degree if any. Since there is a variation in elbow function in every person, one must compare the patient's normal elbow with the injured when arriving at any definite conclusion. A skillful reduction must be performed early, before too much swelling is

pletely. It undoubtedly might be a useful method in fractures that are badly swollen, with blebs in the skin, and those that are twenty-four hours old.

In supracondylar and transcondylar fractures of the humerus, the reduction is carried out under a general anesthetic by a gentle rocking motion of the elbow in hyperextension, properly to align and engage the fragments in the anteroposterior plane, and then hyperflexion so that the fingers of the

FIGURE 4. *The Acute Flexion Position for Fractures of the Elbow, except Those of the Olecranon, Using Adhesive-Tape Fixation, with the Pistol-Holster Sling.*

apparent, and the fixation must hold the reduced fragments in position.

As a general rule, we use the acute flexion position in all elbow fractures except those of the olecranon. We maintain the position by the use of adhesive plaster and the so-called "pistol-holster" sling (Fig. 4), thereby leaving the fingers, hands and radial pulse readily palpable. By untying the sling from behind the neck, the elbow itself is made visible without loss of the fixation. All patients with elbow fractures should be hospitalized for at least twenty-four hours after reduction. Dunlop<sup>11</sup> has described a method of adhesive bed traction with which we have had no experience, but according to Ashurst<sup>6</sup> this should not reduce the distal fragment of the transcondylar type com-

hand rest on the acromioclavicular joint of the shoulder. The arm is held in that position while the bony landmarks are identified and compared with those of the normal elbow in hyperflexion and while the circulation in the fingernails and radial pulse is checked. If reduction is incomplete, the fingers will not rest on the shoulder, and the radial pulse will be lost and the maneuver must then be repeated, thumb pressure on the distal fragment being exerted during the flexion stage. Fluoroscopy is of considerable assistance in cases presenting marked swelling. The maneuver does not require force to attain reduction. Once the adhesive-tape fixation is applied, x-ray films should be taken in both planes, and if the position is good, the pistol-holster sling is applied and

the child put to bed. The postoperative orders should require an hourly check on the pulse and circulation of the wrist, hand and fingers. Among the 58 reductions of transcondylar and supracondylar fractures of the humerus, there was 1 open reduction; furthermore, in 20 of these cases, there was gross displacement, usually medial and posterior, of the distal fragment.

The reduction of fractures of the lateral and medial epicondyles and of the T fracture should be manipulated in much the same way, but one should rely more on digital pressure to replace them. The badly displaced fractures are difficult and require operative reduction and suture in position. Beekman and Sullivan<sup>1</sup> do not hesitate to operate because the carrying angle is so affected by an improperly replaced condyle. With the acute flexion position, it is the tightly drawn fascial envelope of the triceps muscle that holds these fragments in place. Guarded prognoses should always be given in these cases, because the epiphyseal cartilage plate has been damaged.

Fractures of the head and neck of the radius enter the joint, and radical surgery (excision of the head) in a growing child always results in a crippled elbow joint. The healing that takes place in a slightly displaced head of the radius is remarkable, provided the two fragments touch at all, and it is preferable to be ultraconservative. In this series, we had 3 cases of complete displacement of the head from the neck of the radius.

Olecranon fractures in children are rarely complete, with separation of the fragments. This occurred in none of the 4 cases in the series. If separation occurs in the growing child, however, we prefer operative reduction and suture of the overlying fascia; no hardware should be used.

When acute flexion position is utilized, this position and fixation should be maintained for three weeks; of course, the skin should be checked and cared for twice a week during that period. For the following week, a triangle sling is used under the clothing, and the elbow carried at 90° flexion. For the fifth week, the sling is carried outside the clothing, and at six weeks the arm is free. Physiotherapy should never be employed in the convalescent care of elbow fractures in children, and Nature should be allowed her opportunity to absorb excess callus and to improve motion. Forced manipulation should never be used in an attempt to increase motion. End results are not always obtained until eighteen to twenty-four months after the original fracture.

The end results of the 106 fractures of the elbow treated according to these general principles are presented in Table 3. Of the unsatisfactory results

in 8 cases, the fractures were in the head and neck of the radius in 2, in the region of the lateral condyle in 3 (2 of these were old united fractures when the patients came to the hospital and had originally been treated elsewhere), supracondylar in 2 (1 of which was a month old on entry), and an old transcondylar fracture in 1. Therefore, excluding the old fractures, there were 5 unsatisfactory end results in 98 cases of elbow fracture, or an incidence of 5 per cent.

One should face the problem of elbow fractures in children with meticulous care and courage, for

TABLE 3. *Results of Treatment in Fractures of the Elbow.*

on the whole the results are quite satisfactory. The problem of operative correction of bony deformity in a healed elbow fracture is tempting, but it is a better policy to await the full growth of the child before such corrections are attempted. To damage the growing cartilage plate by operative interference because of a false carrying angle or prominent condyle is foolhardy, meddlesome surgery.

In this series of 106 fractures of the elbow in which 102 reductions were carried out, there were

TABLE 4. *Results of Treatment by Open Reduction in Fractures of the Elbow.*

TYPE OF FRACTURE	NO. OF NEW CASES	NO. OF OLD CASES	RESULTS

8 open reductions after attempted closed reduction had failed. The results are given in Table 4. Open reduction was attempted in two old fractures (more than one month after the injury), and in each case there was a poor result. Two out of 3 cases of fractures of the head and neck of the radius with displacement of the fragments resulted poorly. From this small incidence of open

very meager, but in self-sacrifice, nobility of character and wisdom he was in truth a giant.

If I could bring home to you in this dissertation only one sustaining inspiration, it would be the cultivation of the broad understanding that characterized those benevolent family doctors. I am sure, by and large, they never thought in terms of an ethical code, but rather lived their private, as well as their professional, lives in an honorable relation to fellow practitioners and patients. Consequently, the thought that is uppermost in my mind in dealing with medical ethics is, somehow or other, to get you to think of the code, not as a set of rules and regulations, like the by-laws of a state medical society, but rather as professional ideals of duty and obligation.

You will learn, when you get time to indulge yourself in the luxury of reading medical history, that medical ethics go back to the year 2250 B.C. when a Semitic king, Hammurabi, in Babylon, chiseled out a code of ethics on stone tablets. You will often be reminded of the Oath of Hippocrates, which for 2400 years has been the pledge of physicians. How else can we explain the virility of these principles and precepts, which are self-imposed, except by saying that they are based on truth? And may I now remind you that you will soon enter the portals of a profession that has unswervingly adhered to its nobility of purpose since the very beginning of its existence?

I think it would be well to take the time to quote this oath. You may be familiar with it, although I cannot recall having heard it until the day of graduation, and I think the wise and prudent, though departed, Dr. George W. Gay, who sponsored this lecture, expects it. Let me read it to you.

I swear by Apollo, the Physician, by Aesculapius and Health, and All-heal, and all the gods and goddesses, that, according to my ability and judgment, I will keep this oath and stipulation,—to reckon him who taught me this art equally dear to me as my parents, to share my substance with him and relieve his necessities if required; to regard his offsprings as on the same footing with my own brothers and to teach them this art if they should wish to learn it without fee or stipulation; and that by precept, lecture and every other mode of instruction I will impart a knowledge of the art to my own sons and to those of my teachers and to disciples bound by a stipulation and oath according to the law of medicine, but to none other.

I will follow that method of treatment which according to my ability and judgment I consider for the benefit of my patients and abstain from whatever is deleterious and mischievous. I will give no deadly medicine to anyone if asked, nor suggest any such counsel, furthermore I will not give a woman an in-

strument to produce abortion. With purity and with holiness I will pass my life and practice my art. I will not cut a person who is suffering with a stone but will leave this to be done by practitioners of this work. Into whatever houses I enter I will go into them for the benefit of the sick and will abstain from every voluntary act of mischief and corruption and further from the seduction of females or males bond or free.

Whatever in connection with my medical practice or not in connection with it I may see or hear in the lives of men which ought not be spoken abroad, I will not divulge as reckoning that all such should be kept secret. While I continue to keep this oath unviolated may it be granted to me to enjoy life and the practice of the art respected by all men at all times, but should I trespass and violate this oath may the reverse be my lot.

Certainly these are broad principles of moral conduct from the greatest physician of ancient Greece, and you will do well, in your early days of practice, when unwanted leisure may tempt you to much profitless reading, to study his life and writings. I shall not burden you with many references but would recall that he was the first actually to differentiate diseases and by accurate observation and study to divorce sickness from superstition.

Coming down somewhat closer to our time, you will find a book published in 1803 and written by Dr. Thomas Percival to be most eloquent. This is entitled *Medical Ethics: A code of institutions and precepts adopted to the professional conduct of physicians and surgeons*. From this delightful book, which I recommend to you, is derived the code of ethics of the American Medical Association.

Carefully weighing these many admonitions laid down for us in the code and in the great writings of the master minds of medical history, we find constantly re-emphasized the physician-patient relation and the ever-present reminder that our first duty is to our patients. Certainly, you have a duty to other members of the profession, to the public in general and to yourself. Of these, I shall also have something to say presently, but they naturally follow the other in the order of their importance.

Somewhere in my early medical days,—just when or where, I cannot be sure, but probably from Dr. William H. Robey, whose kindly wisdom, advice and guidance, and example did much toward shaping my own career,—I learned that the treatment of a disease is wholly impersonal but that the treatment of a patient is entirely personal, and that a great physician combines in himself the utmost in scientific knowledge and the quality of complete self-sacrifice. Not so long ago I had the pleasure of discussing some of these qualities with Dr. Soma Weiss, who gave it as

his opinion that the basic elements of greatness were "sincerity and genuine sympathy."

Here I need not dwell on your broad training in the medical sciences, which has been well attended to, but I have found in my years of contact with interns that there is often a sad lack of training in the virtues of tolerance, patience and sincerity. The old notion that physicians are born has almost disappeared. They are not born, they are trained, and they are trained for the care of the sick. The attribute of a self-sacrificing desire to restore health as completely and as quickly as possible has characterized all the great doctors of history, even down to this very day, and when you receive your degree in medicine there goes with it this responsibility to the sick.

Not all of you will have the two important prerequisites for greatness in the same proportion. With some it will be more science and with others more art. Accordingly, I should not say that with science alone you cannot be great, for there may be those among you who will go into fields of research and pure scientific investigation, those whose careers completely separate them from the care of the sick, those whose names may shine as brilliantly as that of the late Dr. Frederick G. Banting, who gave us insulin for diabetes. But I most sincerely assure you who will be practitioners that the measure of your success depends ultimately on with what measure of both these components you are blessed.

I suppose one of the most puzzling questions that you as young practitioners will ever ask, your selves will be, How do people pick out a particular physician? or How did so and so ever happen to call me? I have no clear cut answer for these questions. I have long thought about this and tried to evaluate the various elements involved. Salesmanship—and I mean the ability to sell yourself—seems very important. Personality, in the sense of the sum total of character must be equally important, although I am sure that ability and skill may, sooner than you would believe, become the determining factors.

Probably your first actual responsibility to a sick person will come in the hospital wards and a problem that has often come to my mind of late has to do with your handling of patients in house officers, during either your internship or residency. Here I admonish you not to say things, publicly or in the hearing of others, that will hurt the feelings of your patients or frighten them for it serves no good purpose other than to mark you as lacking in kindness and sympathy.

Because of their teaching value, clinics and ward

rounds have become very general, even in the small hospitals widely separated from medical schools. If carefully considered, they can be conducted without emotional damage to the patient, although not always, I fear.

I had a recent experience in a large metropolitan teaching hospital that makes this point clear. I was there for a brief visit with the chief in medicine, one of our greatest present day internists, he turned me over for a short ward round with one of the younger members of his teaching staff, who appeared to be very familiar with his cases and well informed medically. However, he talked freely and openly. It was not a large ward, and everyone in the place knew the most intimate details of the other's histories, both medical and social, except for that of one timid woman of about fifty-five. She was in the next to the last bed, and when we came up to it, the intern gave me her clinical record and pointed to the x-ray report, which showed extensive cancer of the stomach. He said not one word about the case and continued on to the last patient, but his silence was infinitely more eloquent than his previous discussion of the other cases. As he put the record back on the foot of the bed and was about to go on, the poor woman broke into tears and cried out, 'Oh, I am sure I have some terrible disease because you always tell about the others and then whisper about me.' It was no easy job for this physician and myself to quiet her down, and I am sure that we did not begin to undo the damage my visit had caused.

Let you think that this question of the patients' emotional reactions to their examinations on rounds and at clinics is one of very minor importance, I might tell you that at this time in more than one of our major teaching centers, a very serious study of just this problem is being made.

The matter of consultations should find a place in the early part of this presentation because you will not be long, in practice before you will come face to face with this aspect of medical life. You will find a great divergence of opinion among your confreres on the subject, and I can serve you best by presenting it from a personal point of view.

As your years in practice increase, you will most surely fall into one or the other of two general groups: those who seek and desire consultations, and those who spurn and abhor them. It is my counsel that you be in the first group. Confronted with a serious situation, do not risk carrying the entire responsibility, share it with some consultant, preferably one of your own choice. Ask for the

general practice, you will most probably find the office and house fee a well-settled local custom, long before your arrival. In the special fields, this is also true, although in surgery the situation is more flexible. The honorable surgeon will set a fee somewhat according to the patient's means, and this is equally true of consultations. Often it is my custom to ask the doctor who calls me about the family circumstances and even to let him suggest the fee. I do not feel too strongly about this plan, however, for often he sets too low a valuation on the consultation, and experience will teach you that many people value your services at just the price you put on them. Contrasted to this, however, you will find among your true charity cases and your free-ward cases in the hospital those who set a value, much beyond price, on what you do for them. It is an open question to what extent a large income elevates a professional man and to what extent a generally high level of income elevates the whole profession. Material prosperity should be valued in its proper perspective.

Now let me turn from this consideration of duty to your patients and duty to your professional brothers to that of the public in its larger sense. It is not in my mind to discuss public service as it applies to a health officer, a medical officer of the United States Army or Navy or an official of a corporate or tax-supported institution or government department, but specifically, to dwell for a few moments on another aspect of the life of the practitioner.

In alluding to some of these, it might be well to dispose first of a question often raised by the laity and to some extent believed by them, namely, Is a physician legally obliged to respond to a professional call from anyone? If the call comes from complete strangers, or from those whom you never previously attended for an illness that might be linked to this call, it may be unreservedly stated that you have no responsibility to accept such a case. But should you choose to go in response to such a summons and engage in the case, you do acquire a legal responsibility, for you have become a party to an implied, even though unwritten, contract, and you will be subject under all the laws and statutes applicable to contracts, even to defending yourself in a court of law for any breach thereof. This being so, there remains, nevertheless, the certainty that the true physician has ever been ready and willing to respond in an emergency, for it is quite obvious that any physician would be more helpful than a lay person, even those who have for years limited their practice and studies to a special branch. Such a situation was my experience a few years

ago when I came on the scene of an automobile accident and found the person who was adjusting a pillow and side splint to a fractured lower leg to be the senior eye specialist of our hospital; in talking it over with me later, he told me what a pleasure he got out of doing it, although I am sure he never learned the victim's name, much less got a fee for his trouble.

Another duty to the public on which I am inclined to dwell somewhat, is one, if you will permit me to say so, with which I have had considerable experience. It is your appearing before courts of law and boards of adjudication. This is a duty that you cannot hope to escape, for on a day when it seems that nothing more can be heaped on you in the way of other people's troubles, there will come into your consulting room a large and rather sober-looking man. Just as you are about to offer him your comfortable desk-side chair and ask him his name for your clinical record, he will reach into an inside pocket and produce, like a rabbit out of a hat, a court summons demanding your appearance in court at 9 a.m. the next day. This hour, curiously enough, will be the very time you had reserved at the hospital for a tonsillectomy.

Few of you who are going into general practice, or even the specialties, will have quite enough of this to give you a feeling of being at home on the witness stand, and since it is a matter of some importance to your pride that you acquit yourself with credit, both personally and professionally, I venture this concise advice: be scrupulous in your honesty. No doctor on the witness stand who keeps this in mind is ever in trouble, although I concede the difficulty of not being biased, either for your patient or for the insurance company that employs you. To this might be added the desirability of keeping your answers as simple as the purport of the query permits, the uselessness of volunteering information not asked for and, finally, the value of preparing yourself for testifying by familiarizing yourself with the factors involved, as they relate to medicine in general and the case in particular. It matters little how clever and menacing the cross-examiner; he is a lawyer, and although he may have a well-deserved legal reputation and a large medical vocabulary, you are a physician, skilled in the field about which you are testifying, not deviating from the known facts, and not afraid to say, "I don't know."

It was my good fortune very early in my medical life to have had a word of advice on this matter from Dr. Timothy Leary. While I was a house officer at the Boston City Hospital, an unconscious patient was admitted who obviously was

dying of meningitis. A lumbar puncture proved it to be a pneumococcal meningitis. We had no serum or sulfathiazole in those days, and the patient died in a few hours. It so happened that the patient had been in a street fight the previous day, and on this basis it became a medico-legal death; Dr Leary, who was the medical examiner, autopsied the man and found a skull fracture through the temporal bone and the probable point of entry for the pneumococci. The other details are unimportant, but there was a political angle to the case, and it finally developed into a charge of manslaughter. Presently I was summoned into court; this was my first experience, and you may rightly suspect that I was nervous, because my testimony was important in linking this death with Dr. Leary's findings. When I met Dr. Leary in the corridor of the courthouse, I told him how nervous I was and asked him what advice he could give me, since it was my first appearance in court as a witness. His counsel I pass on to you: "Tell the truth and don't deviate from it, no matter what they ask you. If you don't know, say so; don't quibble and don't split hairs."

It is probable that in the course of your practice, you will often be called on for health certificates, disability statements and compensation forms, and, at the moment, there are those who seek a statement that they have a disability that will exempt them from military training. Surely by now, there is nothing for me to add in this regard, for your self-imposed rule of conduct in all your dealings with your fellows will be the guide.

It may be that I should add a word or two about advertising, which, I believe, is in much the same position as fee splitting. In New England it just is not done, or if it is, it has quite escaped my observation. You may occasionally need a modest and dignified notice in the local paper on your return to practice following a reasonably long absence, and this is quite proper; but conscious and deliberate advertising should be generously left to the cultists and quacks.

Publicity seeking, however, is quite a different matter and a much more insidious disease. In calling your attention to it, let it be assumed that you recognize I allude to the pursuit of this siren, who may well lure you from your high purpose to the rocks of mediocrity. Your measure of greatness may well be the relative rarity with which your name appears in the daily press and the frequency of its appearance in the *Quarterly Cumulative Index*. In no sense does this statement imply that when you have reached a

position of prominence and importance in your community you will demand anonymity; rather, it is my hope that it will suggest which of these two points of view has in it attributes of greatness. You will be expected, from time to time, to lend the authority of your name to a radio talk, which, when properly sponsored, is completely ethical; in fact, it might rightfully be considered among your duties to the public, for we are the ones to educate laymen in matters that pertain to their health. It is a vast and tremendously interested audience that listens to physicians on the radio. If kept within proper limitations, this activity does much to counteract the mischief of the cults.

Passing from these responsibilities to the public, consider with me the more intimate and personal aspects of medical life, which I have chosen to call "duties to yourself." The public will demand much of you, organized medicine its share, and your patients practically all of you; therefore, it is to those things that contrast you with others of our profession, also serving this triad of taskmasters, that I shall turn my attention.

I might enumerate a long list of "don't's," such as dressing flashily, driving around in a brightly automobile and not keeping your person and office businesslike, but I incline to the general belief that you are well informed on these matters from your own observation and general knowledge. Furthermore, I do not intend to spend much time in stressing the importance that attaches to the possession of a good professional manner. This you will acquire in just the right proportion, as you respect the dignity of your calling. Perhaps the Vandylke beard and the Prince Albert coat did enhance the professional air of those doctors of a former generation. However, I think you need not worry about acquiring a silk hat as a badge of your profession, lest your patients think that you have just dropped in on your way to a wedding or a funeral.

My concern is more with your acquiring a continuing medical capacity. You have, by now, become aware of the inescapable fact that medical knowledge is never static, that many times you must unlearn and relearn the management of a given disease, in the light of new information and discoveries. If you review the papers written on diabetes by such an authority as Dr. Elliott P. Joslin, in the space of his professional experience, you will see the truth of this statement.

Presently many of you will be starting or seeking internships. In my medical school days only a part of the graduates took intern training. I

## DISSECTING ANEURYSM OF THE AORTA

## Report of a Case

CHRISTOPHER C. SHAW, M.D.,\* AND HARRY T. FRENCH, M.D.†

BELLOWS FALLS, VERMONT, AND HANOVER, NEW HAMPSHIRE

DISSECTING aneurysm of the aorta was first described more than two hundred years ago by a British physician named Nicholls,<sup>1</sup> who demonstrated in 1728 that rupture of the inner coat of the aorta could occur without rupture of the outer coat, an aneurysm developing within the middle layer. The same physician in 1761 performed an autopsy on the body of King George II, of England, who had died suddenly while straining at stool. Nicholls found a dissecting aneurysm of the aorta, which by pressure on the pulmonary artery had caused rupture of the right ventricle and sudden death. The great anatomist, Morgagni,<sup>2</sup> recognized dissecting aneurysms and described an autopsied case as early as 1769. A striking account of a dissecting aneurysm occurring during labor was reported by Lynn<sup>3</sup> in 1798. The master French clinician, Laënnec,<sup>4</sup> was familiar with this condition, to which he applied the term, "aneurysma dissecans," in 1819. The first correct ante-mortem diagnosis was made in 1856 by Swaine.<sup>5</sup>

Although 500 cases of rupture of the aorta appeared in the literature during the next eighty years, in only 9 was a correct ante-mortem diagnosis made until the subject was carefully reviewed by Osgood et al.,<sup>6</sup> and by Peery<sup>7</sup> in 1936 and independently studied a year later by McGeachy and Paullin,<sup>8</sup> who reported 3 cases of their own, with correct diagnosis before death. As a result of these recent analytic clinical studies, interest in the condition has received renewed impetus during the last three or four years, and reports of accurate ante-mortem diagnoses are no longer a rarity. However, since dissecting aneurysm of the aorta is found with increasing frequency and since this condition may be readily confused with coronary thrombosis, we believe that a short outline of the clinical features of dissecting aortic aneurysm, with an illustrative case diagnosed on the first day of the disease, will not be amiss.

The clinical picture may be confusing because of the severity of the onset, which may make a detailed examination impossible, and because of the rapid sequence of alarming symptoms, which

spell a fatal termination in twenty-four hours or less in more than 75 per cent of the patients. Sudden death is almost a common denominator and often occurs before diagnosis can be made. More recently, a chronic form of the disease, presenting symptoms of progressive decompensation simulating cardiovascular syphilis, has been recognized. In 4 such cases reported by Gouley and Anderson,<sup>9</sup> the patients did not complain of any pain whatever during the entire course of their disease, which varied in duration from two months to four years.

A dissecting aneurysm develops as a result of the rupture of the intimal lining of the aorta a short distance above the valve ring, either at the site of an arteriosclerotic plaque<sup>7</sup> or at the locus of rupture of one of the vasa vasorum.<sup>10</sup> In either event, the lesion is associated with arteriosclerotic or cystic changes in the elastic tissue of the media (necrosis media aortica cystica).<sup>11</sup> Degeneration of the media, possibly owing to metabolic toxins, leads to intramural changes and thus paves the way for dissection by the aneurysm.<sup>12</sup> This condition is not limited to the aorta alone, since it is primarily a disease of blood vessels with elastic tissue and may therefore appear in the subclavian or iliac arteries, or both. Blood from the lumen is forced through the tear in the intima into the medial coat, where dissection begins at once and progresses very rapidly depending on the height of the systolic pressure and the extent of the cystic degeneration of the elastic tissue in the middle third of the media. The sudden rupture of the intima, with tearing of the medial coat of the aorta, permits the blood to dissect its way between the layers of the media along the entire course of the aorta or outward within the medial coat of the subclavian arteries or downward within the iliac arteries.

This aneurysmal extravasation of blood under high pressure is usually precipitated by emotional excitement or sudden physical exertion. The onset is accompanied by exquisite pain and often by extreme shock, which in itself may be fatal. At first the pain is either thoracic or epigastric, then rapidly spreads downward to the lower abdomen or to the lumbar region and the legs. Vomiting may be associated with the epigastric

†Head of the Department of Medicine, Hitchcock Clinic, Hanover, New Hampshire.

pain, but usually there is little or no abdominal rigidity. As the aneurysm dissects its path between the coats of the aorta, impairment of the circulation to and from the adjacent viscera gives rise to a host of symptoms. Cyanosis and engorgement of the thoracic veins may result from pressure of the aneurysm on these blood vessels. Inefficiency of the cerebral circulation may be noted, owing to involvement of the carotid or innominate arteries. Inequality of the blood pressure may occur in the two arms. Paralysis of the left recurrent laryngeal nerve is not uncommon; dysphagia due to esophageal pressure has been re-

ported. Dyspnea resulting from crowding of the left lung is a fairly frequent finding. Left-sided pleural effusion or collapse of the left lower lobe may occur because of pressure of the aneurysm in this region. Partial occlusion of the renal arteries often gives rise to hematuria, followed by anuria. Further dissection of the aneurysm downward toward the iliac region embarrasses the peripheral circulation in the limbs, as shown by progressive failure of motor power in the lower extremities. The pulsation of the dorsalis pedis artery may be lost in one or both feet. Blood pressure readings in the right and left popliteal regions may show wide discrepancies. The legs become cold, cyanotic and flaccid. Gangrene has been reported as a terminal affair, although few patients live long enough to develop this complication. Impairment of the circulation of the lower extremities has been thought to be due to involvement of the lower intercostal and lumbar branches of the aorta to the anterior and posterior spinal vessels, the dissection thus interfering with the circulation of the spinal cord.<sup>13</sup> Inequality of the blood pressure determinations in the legs may result from constriction of the lumen of the iliac artery as the aneurysm dissects its way within and between the layers of the medial coat.

Aneurysm of the aorta is typically excruciating in character and may be described by the patient as a rending, tearing or rupturing sensation over the precordium, between the scapulas, in the neck, in the epigastrium or in the lumbar region. The pain spreads from the front to the back or vice versa, and usually from the chest to the abdomen and back and down the legs. Rarely does it radiate to the arms. In the atypical form, the "mystery" may be mild, indefinite and intermittent, or conspicuous by its absence.<sup>3</sup> On the other hand, the pain may be excruciating in character and entirely localized below the diaphragm, and may

TABLE 1. *Differential Diagnosis of Dissecting Aneurysm of the Aorta and Coronary Thrombosis*

SYMPTOMS AND FINDINGS	DISSECTING ANEURYSM	CORONARY THROMBOSIS
Onset	Sudden tearing, terrific	Oppression develops slowly
Occurrence	Exertion usually precipitates initial pain	May come on while the patient is at rest
Location of pain	High in chest behind sternum (may be entirely abdominal or referred only to the lower extremities)	Fairly low in the chest
Radiation of pain	To the back in the thoracic or lumbar region	To the neck and left inner arm
Cardiac friction rub	Absent	May appear in a few hours
Roentgen findings	Aneurysmal shadow (may extend along a cervical vessel)	Normal mediastinum
Heart	Usually enlarged (previous hypertension)	May be of normal size
Electrocardiography	Inconstant changes (if any)	Characteristic changes
Circulatory block of an extremity	Common but transient	Uncommon embolic and permanent
Central nervous system symptoms	Paralysis may be partial and progressive or complete (hemiplegia)	Absent; apprehension often a prominent feature
Pleural effusion	Fairly frequent	Very rare (except in chronic decompensation)
Vasodilator drugs	No effect	May relieve anginal syndrome

ported. Dyspnea resulting from crowding of the left lung is a fairly frequent finding. Left-sided pleural effusion or collapse of the left lower lobe may occur because of pressure of the aneurysm in this region. Partial occlusion of the renal arteries often gives rise to hematuria, followed by anuria. Further dissection of the aneurysm downward toward the iliac region embarrasses the peripheral circulation in the limbs, as shown by progressive failure of motor power in the lower extremities. The pulsation of the dorsalis pedis artery may be lost in one or both feet. Blood pressure readings in the right and left popliteal regions may show wide discrepancies. The legs become cold, cyanotic and flaccid. Gangrene has been reported as a terminal affair, although few patients live long enough to develop this complication. Impairment of the circulation of the lower extremities has been thought to be due to involvement of the lower intercostal and lumbar branches of the aorta to the anterior and posterior spinal vessels, the dissection thus interfering with the circulation of the spinal cord.<sup>13</sup> Inequality of the blood pressure determinations in the legs may result from constriction of the lumen of the iliac artery as the aneurysm dissects its way within and between the layers of the medial coat.

The initial pain associated with a dissecting aneurysm of the aorta is typically excruciating in character and may be described by the patient as a rending, tearing or rupturing sensation over the precordium, between the scapulas, in the neck, in the epigastrium or in the lumbar region. The pain spreads from the front to the back or vice versa, and usually from the chest to the abdomen and back and down the legs. Rarely does it radiate to the arms. In the atypical form, the "mystery" may be mild, indefinite and intermittent, or conspicuous by its absence.<sup>3</sup> On the other hand, the pain may be excruciating in character and entirely localized below the diaphragm, and may

thus present the clinical picture of an acute surgical abdomen.<sup>14</sup> But as a rule, a wide, rapidly progressing spread of pain is almost pathognomonic. Shock and collapse are common, and dissecting aneurysm of the aorta is a more frequent cause of sudden death than is generally realized.

This disease occurs usually after the age of fifty, oftener in men than in women, and is found in patients with high blood pressure and extensive arteriosclerosis. The average frequency of this condition at autopsy is 1 case in 630.<sup>15</sup> In the majority of patients, the blood pressure remains elevated throughout the disease, and the higher the degree of hypertension the more rapidly the aneurysm dissects its way downward along the aorta. The clinical picture often resembles the syndrome of coronary thrombosis, but the sudden and dramatic onset of thoracic pain and the persistent hypertension in the presence of shock should lead one to suspect a dissecting aneurysm of the aorta.<sup>16</sup> The x-ray, fluoroscopic and electrocardiographic findings aid in establishing the diagnosis if the patient is not too ill to submit to these procedures. If the patient is in extremis, the correct diagnosis may be most difficult. Indeed, the history alone may be of great value in such cases. When no accurate his-

tory is obtainable, one must consider and rule out pulmonary embolism, spontaneous pneumothorax, ruptured peptic ulcer, cholelithiasis, renal calculus, rupture of a mediastinal abscess and hemorrhage from a new growth in this area. Perforation of a saccular aneurysm and cerebral hemorrhage should not be lightly discarded from the examiner's mind. To clarify the situation, Table 1 presents an outline of the main points of difference between dissecting aneurysm and coronary thrombosis.

The following case illustrates some of these points, since the diagnosis was suspected a few hours after the onset of the initial attack and was confirmed by x-ray films and electrocardiograms later the same day. Post-mortem examination on the nineteenth day of the disease revealed a dissecting aneurysm of the aorta, with death due to rupture of the aneurysm into the left pleural sac.

#### CASE REPORT

A. P. W., a 63-year-old banker, was suddenly stricken with terrific pain in the chest and back at 11:15 a.m. on March 11, 1940, while sitting at his desk. An emergency call was sent to his physician, who saw him within 5 minutes after the onset of the attack. The patient complained of unbearable substernal pain radiating posteriorly between the scapulas and to the right upper quadrant. He stated that at first the pain struck him in the chest and then rapidly shifted to the back and side. His color was ash gray, and he appeared to be going into a state of shock. He was very restless, and begged to lie down on the floor of his office. The pulse rate was only 48; the blood pressure was not taken at that time because the patient broke out in cold perspiration, lost consciousness, and looked as though he were going to die at once. However, he roused partially and complained bitterly of substernal and subscapular agony.

The patient's father had died of arteriosclerosis at the age of 63; his mother succumbed at 28 years to meningitis. One brother and 2 half-sisters were living and well.

The patient stated that he had always been in good health. It was learned from his wife, however, that at the age of 30, he had been ill for a year with "heart trouble" and that he had had to be "careful" for the rest of his life. The exact nature of this trouble could not be determined, but may have been an endocarditis or aortitis. One of us (C. C. S.) had seen him several times off and on because of minor complaints for the previous 4 or 5 years. At no time within this period was there any evidence of cardiovascular disease or hypertension. The blood Wassermann reaction was negative, and there were no clinical signs or symptoms of syphilis.

The patient was given a perle of amyl nitrite by inhalation and a 1/150-gr. tablet of nitroglycerin under the tongue. Since this produced no relief, 1/4 gr. of morphine and 1/100 gr. of atropine were given hypodermically. While the patient was waiting for the ambulance, the pain and shock increased to an alarming degree, and he was therefore given another 1/4 gr. of morphine by mouth, but with little effect.

The patient was admitted to the Rockingham Hospital within less than 1/2 hour after the onset of the attack, with a tentative diagnosis of coronary thrombosis. His

condition appeared to be very critical. The unbearable pain in the chest, back, and right upper quadrant still continued, and there was marked cyanosis of the lips and fingernails. The pulse rate was then found to be 56, and the blood pressure 222/70. The patient received 20 cc. of aminophylline solution intravenously, which brought the pulse rate up to 72 but did not relieve the precordial pain.

FIGURE 1. X-Ray Film of Chest.

*This film, taken with a portable machine on the first day of the disease, shows definite widening of the aortic arch in the region of the transverse and descending aorta.*

He was therefore given another 1/4 gr. of morphine hypodermically and placed in an oxygen tent. He did not tolerate the tent well because of restlessness, and it was thought best to administer sufficient morphine to control his suffering. At 1:00 p.m., he received a fourth 1/4-gr. dose of morphine, which was repeated at 2:45 p.m. In other words, 1 1/4 gr. of morphine was necessary within 3 hours to quiet the patient. Nitroglycerin, 1/100 gr., was given under the tongue as often as necessary to obtund his pain. The systolic blood pressure, however, failed to fall below 220. The patient appeared to be too ill to submit to physical examination for several hours.

The admission diagnosis of coronary thrombosis was considered untenable because of the extreme severity and continuance of pain in spite of massive doses of morphine and the nitrites. Moreover, the persistent bradycardia and the hypertension in the presence of pronounced shock were very atypical of coronary thrombosis. Because of the general picture, the likelihood of a dissecting aneurysm of the aorta was suggested by his physician (C. C. S.) and the consultant (H. T. F.). This diagnosis was supported by an electrocardiogram, which was negative except for inversion of T<sub>1</sub> and by a roentgenogram (Fig. 1), which showed a probable dilatation of the descending aorta.

Examination of the blood on admission revealed a red cell count of 4,620,000 with a hemoglobin of 85 per cent, and a white-cell count of 10,100 with 80 per cent polymorphonuclear leukocytes.

The patient ran a septic type of temperature for the 1st week. During this period he was very critically ill,

and the higher his temperature, the graver was his condition. On the 8th, 9th and 10th days of hospital residence, he remained afebrile and showed gradual improvement. From the 12th to 19th days, the fever reappeared, probably owing to further dissection of the aneurysm, and the prognosis became more guarded.

The hypertension present on admission persisted for 2 days. On March 13, the blood pressure reading was within normal limits, 160/84. On March 14, there was a sudden rise of the temperature to 101°F, with extreme back pain and a concomitant fall in the blood pressure to 90/60 as the patient again sank into a state of shock. It was believed that the aneurysm had dissected and torn its way through the aortic hiatus of the diaphragm, because the pain in the region of the mid back was excruciating. The patient rallied following the administration of stimulants, and the next day presented marked icterus of the skin and sclerae.

On March 12, marked dullness on percussion was elicited in the interscapular area on both sides of the spine. Over this region one could hear a faint, low pitched and continuous roar that was not associated with or affected by the respiratory sounds over the lung hili. Over the course of days, the dullness gradually increased in extent and the bruit in intensity, until both could be heard distinctly from the pulmonary apices to the sacrum over the paravertebral regions. No visible or palpable pulsations were noted posteriorly at any time, and the patient was too sick to be fluoroscoped during his entire illness.

Auricular fibrillation set in on March 13, but responded promptly in rapid digitalization. The normal rhythm was occasionally interrupted by showers of extrasystoles, although the digitalis was reduced to a maintenance dose of 1½ gr daily beginning March 15. Accentuation of the second pulmonic sound became marked, and reduplication of the first sound appeared over both the aortic and pulmonic areas. This gave way to a systolic murmur over the mitral, aortic and pulmonary valves. On March 20, a tender pulsating mass appeared in the right lower quadrant of the abdomen. Duroziez's sign was prominent over this pulsating tumor, which disappeared 2 days later. The left border of cardiac dullness on percussion was found to be in the 6th interspace, 135 cm from the mid line. The cardiac sounds finally became loud and booming and could be heard readily throughout the entire chest and abdomen, both anteriorly and posteriorly. The head and neck were seen to jerk and throb with each systole. On March 29, the day before death, a large, tender, pulsating mass appeared in the left upper quadrant, rapidly filled this area and ballooned outward to the level of the umbilicus. A loud bruit was present over this tumor, which was thought to be a portion or a knob of the aneurysm, since no splenic notch could be felt and the blood picture remained essentially normal.

Probably the most interesting finding on physical examination was the discrepancy in the blood pressures in the two lower extremities. On March 15, a second electrocardiogram revealed inversion of T<sub>2</sub>, with T<sub>4</sub> biphasic. On this same day it was noted that the pulsation of the dorsalis pedis artery was more pronounced in the left foot than in the right. Unfortunately, comparative blood pressure determinations in the legs were not made until 3 days later, when the reading in the left leg was 249/106 and in the right leg 156/104. This discrepancy was still present on March 22, when readings of 244/105 and 140/98 were obtained in the left and right legs respectively. On March 25, identical readings (182/90) were found in each extremity.

Two days later, the patient's general condition seemed quite encouraging, and it was hoped that his improvement might continue. Since the pulsating mass in the right lower quadrant was no longer present and since the blood pressure readings had become equalized of their own accord, it was hoped that the periaortic aneurysm had dissected back into the main aortic channel just above the level of the iliac bifurcation, forming the so-called "double barrelled aorta." If this surmise had been correct, it was thought that a fatal outcome might be postponed for a considerable length of time.

On March 26 and 29, however, diarrhea and gaseous distention became increasingly distressing. A large, tender, pulsating mass appeared in the left upper quadrant, rapidly filling the epigastrium and extending down to the level of the umbilicus. There was no change in the blood pressure or in the blood picture, but the temperature rose to 101°F. It was believed that this condition was due to further dissection of the aneurysm below the diaphragm, the prognosis therefore became very uncertain.

Early on the morning of March 30, the patient experienced mild precordial pain, which was relieved by amnophylline. At 8:00 a.m., he stated that he felt fine and had no pain. Forty minutes later, he suddenly went into shock, and died while lying quietly in bed. The respirations persisted spasmodically for at least 3 minutes after the heart ceased beating. The picture during the agonal stage was one of exsanguination.

The final clinical diagnosis was dissecting aneurysm of the aorta, with death due to rupture of the aneurysm and massive internal hemorrhage.

**Autopsy.** Post mortem examination, performed 8 hours after death by Drs. R. E. Miller and W. M. Downing, of Hanover, New Hampshire, showed an extensive retroperitoneal hemorrhage to the left of the mid line from the splenic flexure of the colon down to the perirenal region and into the left portion of the pelvis. The peritoneum in these areas was dark red and purple owing to the underlying blood, but there was no evidence of intraperitoneal hemorrhage.

The right pleural cavity was dry, smooth and glistening. In the left pleural cavity, approximately 3 liters of hemorrhagic material, with massive blood clots in the dependent portion, was present. At the junction of the arch of the aorta with its ascending portion, an orifice 0.5 cm in diameter was encountered, which communicated with the left pleural cavity. This was the point of rupture of the dissecting aneurysm. The pericardium was not involved, and the heart itself appeared essentially normal with the exception of sclerosis of the aortic valve (Grade II), and extensive sclerosis of the root of the aorta and of the coronary arteries (Grade III). The peritoneal tissue in the lumbar regions and the perirenal fat on the left side were found to be heavily infiltrated with hemorrhagic material. At the point where the left subclavian artery arose from the arch of the aorta, there was a break in the intima of the aorta forming an orifice 0.3 cm in diameter that communicated with a space in the peritoneal adventitia extending from the region of the left subclavian artery down to the point of bifurcation of the common iliac vessels (Fig. 2). This peritoneal space did not completely surround the aorta at any point, but was filled with clotted blood. Five centimeters distal to the intimal rupture marking the origin of the dissecting aneurysm was located the point of rupture of the aneurysmal sac into the left pleural cavity. The peritoneal clot surrounding the right common iliac artery was so large that the true lumen of the vessel was markedly narrowed.

tory is obtainable, one must consider and rule out pulmonary embolism, spontaneous pneumothorax, ruptured peptic ulcer, cholelithiasis, renal calculus, rupture of a mediastinal abscess and hemorrhage from a new growth in this area. Perforation of a saccular aneurysm and cerebral hemorrhage should not be lightly discarded from the examiner's mind. To clarify the situation, Table 1 presents an outline of the main points of difference between dissecting aneurysm and coronary thrombosis.

The following case illustrates some of these points, since the diagnosis was suspected a few hours after the onset of the initial attack and was confirmed by x-ray films and electrocardiograms later the same day. Post-mortem examination on the nineteenth day of the disease revealed a dissecting aneurysm of the aorta, with death due to rupture of the aneurysm into the left pleural sac.

#### CASE REPORT

A. P. W., a 63-year-old banker, was suddenly stricken with terrific pain in the chest and back at 11:15 a.m. on March 11, 1940, while sitting at his desk. An emergency call was sent to his physician, who saw him within 5 minutes after the onset of the attack. The patient complained of unbearable substernal pain radiating posteriorly between the scapulas and to the right upper quadrant. He stated that at first the pain struck him in the chest and then rapidly shifted to the back and side. His color was ash gray, and he appeared to be going into a state of shock. He was very restless, and begged to lie down on the floor of his office. The pulse rate was only 48; the blood pressure was not taken at that time because the patient broke out in cold perspiration, lost consciousness, and looked as though he were going to die at once. However, he roused partially and complained bitterly of substernal and subscapular agony.

The patient's father had died of arteriosclerosis at the age of 63; his mother succumbed at 28 years to meningitis. One brother and 2 half-sisters were living and well.

The patient stated that he had always been in good health. It was learned from his wife, however, that at the age of 30, he had been ill for a year with "heart trouble" and that he had had to be "careful" for the rest of his life. The exact nature of this trouble could not be determined, but may have been an endocarditis or aortitis. One of us (C. C. S.) had seen him several times off and on because of minor complaints for the previous 4 or 5 years. At no time within this period was there any evidence of cardiovascular disease or hypertension. The blood Wassermann reaction was negative, and there were no clinical signs or symptoms of syphilis.

The patient was given a perle of amyl nitrite by inhalation and a 1/150-gr. tablet of nitroglycerin under the tongue. Since this produced no relief, 1/4 gr. of morphine and 1/100 gr. of atropine were given hypodermically. While the patient was waiting for the ambulance, the pain and shock increased to an alarming degree, and he was therefore given another 1/4 gr. of morphine by mouth, but with little effect.

The patient was admitted to the Rockingham Hospital within less than 1/2 hour after the onset of the attack, with a tentative diagnosis of coronary thrombosis. His

condition appeared to be very critical. The unbearable pain in the chest, back, and right upper quadrant still continued, and there was marked cyanosis of the lips and fingernails. The pulse rate was then found to be 56, and the blood pressure 222/70. The patient received 20 cc. of aminophylline solution intravenously, which brought the pulse rate up to 72 but did not relieve the precordial pain.

FIGURE 1. X-Ray Film of Chest.

*This film, taken with a portable machine on the first day of the disease, shows definite widening of the aortic arch in the region of the transverse and descending aorta.*

He was therefore given another 1/4 gr. of morphine hypodermically and placed in an oxygen tent. He did not tolerate the tent well because of restlessness, and it was thought best to administer sufficient morphine to control his suffering. At 1:00 p.m., he received a fourth 1/4-gr. dose of morphine, which was repeated at 2:45 p.m. In other words, 1 1/4 gr. of morphine was necessary within 3 hours to quiet the patient. Nitroglycerin, 1/100 gr., was given under the tongue as often as necessary to obtund his pain. The systolic blood pressure, however, failed to fall below 220. The patient appeared to be too ill to submit to physical examination for several hours.

The admission diagnosis of coronary thrombosis was considered untenable because of the extreme severity and continuance of pain in spite of massive doses of morphine and the nitrites. Moreover, the persistent bradycardia and the hypertension in the presence of pronounced shock were very atypical of coronary thrombosis. Because of the general picture, the likelihood of a dissecting aneurysm of the aorta was suggested by his physician (C. C. S.) and the consultant (H. T. F.). This diagnosis was supported by an electrocardiogram, which was negative except for inversion of T<sub>4</sub> and by a roentgenogram (Fig. 1), which showed a probable dilatation of the descending aorta.

Examination of the blood on admission revealed a red-cell count of 4,620,000 with a hemoglobin of 85 per cent, and a white-cell count of 10,100 with 80 per cent polymorphonuclear leukocytes.

The patient ran a septic type of temperature for the 1st week. During this period he was very critically ill,

ned. Although their cases were not typed, rains subjected to serologic classification all their into Group 1 or into what they called 1-3. The serums included both concentrated and unconcentrated lots, but all of them had high titers of antibodies (by the various criteria used) against the particular type occurred in this series. They also used larger of serum, and this may have been an important factor in the low mortality.

determining the value of antimeningococcus serum, one is thus left with a peculiar impression similar to that following the early use of pneumococcus serums, namely, that one is dealing with an agent that is apparently effective, conclusive proof of its effectiveness is lacking.

Of those who used the serums noted the clinical improvement in the patients who died; the best results occurred in the cases died early and in the young patients, except in the cases. Nevertheless, considerable conflicting concerning mortality in different communities, and at different times in the same community, leave an element of doubt concerning the relation the drop in mortality ascribed to the use of serum actually has had to the variations in disease at a particular time and place. The use of antimeningococcus serums is already involved in many of the same problems that later concerned workers concerned with the treatment of pneumonia: type variations, differences in mortality among the types and in different age groups, variations in the potency of serums and difficulty in estimating such potency by laboratory tests, the results of which have any correlation with clinical efficiency.

#### ANTERIOR POLIOMYELITIS

The problem of evaluating the use of convalescent serum in the treatment of anterior poliomyelitis presents an even more complex situation. In the first place, there is involved a serum that experimentally has been shown to have only what has been called "neutralizing antibodies."<sup>16</sup> There is no evidence that convalescent serums or antisera prepared against the virus in experimental animals are of any value in curing disease or in preventing paralysis even in animals, once the infection has taken hold. It is obvious that human beings cannot be treated at the same time that the virus is introduced. Therefore, theoretically, convalescent serum has no standing as a therapeutic agent, even on an experimental basis. Nevertheless, it has been accepted widely. It was only after experiments had been made to reinvestigate the problem by carefully controlling the results that any

element of doubt concerning the value of the serum was introduced.

In this disease, the mortality has shown wide variations in different epidemics, and even within the same epidemic in different communities. Similar variations in extent and severity of the paralysis have occurred during the same epidemic. Comparisons between cases that were serum treated and those that were not have been most difficult. One is dealing with a therapeutic agent accepted more or less on faith and used because in this disease no other effective therapy is available. The results, as reported, have been accepted without criticism. In 1932, Kramer and his associates<sup>17</sup> presented the results of their experiments in Brooklyn, and Park,<sup>18</sup> at the Association of American Physicians, presented the results of a large experiment undertaken jointly by the New York City Department of Health and the New York Academy of Medicine. These studies indicated that in two large contemporary series of cases the mortality and the extent of paralysis were almost identical, and, in fact, that the differences observed were slightly unfavorable for the serum-treated cases. The results were disbelieved by some workers and merely ignored by others,\* but they have since been confirmed.<sup>19</sup>

#### PNEUMOCOCCAL PNEUMONIA

Before turning to the immediate problem concerning pneumonia, one should consider some of the factors that are involved in determining the therapeutic efficacy of an antiserum for human patients after its beneficial effects in experimental animals have been clearly demonstrated. The chief factors may be listed as follows: the problem of diagnosis, including both the clinical and the etiologic diagnosis; the factors in the parasite or the invader; the factors in the host; the factors concerning the antiserum; the extent to which the host and the invader have interacted at the time when the antibody is administered; and the complications of the infection.

In diphtheria, the diagnostic problems are not very difficult. Treatment usually can be administered on the basis of clinical diagnosis, and the etiologic diagnosis is not too difficult to establish or to verify. The host is usually a young person, and complicating conditions in the host are not important factors. In infants, the prognosis is poor, as in most other severe infectious, and

\*Here again, one observes the mixed motives that sometimes confront the laboratory scientist when he is concerned with clinical experimentation. In discussing Park's paper, Flexner<sup>19</sup> stated "There is a consensus . . . that the use of convalescent serum does no harm. Since it cannot be affirmed that in an individual case it does no good, should its use be withheld? This is a question to be answered not by a pathologist but by a practitioner." Many a budding clinician hoping to bring a strict "scientific attitude" to bear on some of his bedside problems felt a bit disturbed by these remarks.

tory is obtainable, one must consider and rule out pulmonary embolism, spontaneous pneumothorax, ruptured peptic ulcer, cholelithiasis, renal calculus, rupture of a mediastinal abscess and hemorrhage from a new growth in this area. Perforation of a saccular aneurysm and cerebral hemorrhage should not be lightly discarded from the examiner's mind. To clarify the situation, Table 1 presents an outline of the main points of difference between dissecting aneurysm and coronary thrombosis.

The following case illustrates some of these points, since the diagnosis was suspected a few hours after the onset of the initial attack and was confirmed by x-ray films and electrocardiograms later the same day. Post-mortem examination on the nineteenth day of the disease revealed a dissecting aneurysm of the aorta, with death due to rupture of the aneurysm into the left pleural sac.

#### CASE REPORT

A. P. W., a 63-year-old banker, was suddenly stricken with terrific pain in the chest and back at 11:15 a.m. on March 11, 1940, while sitting at his desk. An emergency call was sent to his physician, who saw him within 5 minutes after the onset of the attack. The patient complained of unbearable substernal pain radiating posteriorly between the scapulas and to the right upper quadrant. He stated that at first the pain struck him in the chest and then rapidly shifted to the back and side. His color was ash gray, and he appeared to be going into a state of shock. He was very restless, and begged to lie down on the floor of his office. The pulse rate was only 48; the blood pressure was not taken at that time because the patient broke out in cold perspiration, lost consciousness, and looked as though he were going to die at once. However, he roused partially and complained bitterly of substernal and subscapular agony.

The patient's father had died of arteriosclerosis at the age of 63; his mother succumbed at 28 years to meningitis. One brother and 2 half-sisters were living and well.

The patient stated that he had always been in good health. It was learned from his wife, however, that at the age of 30, he had been ill for a year with "heart trouble" and that he had had to be "careful" for the rest of his life. The exact nature of this trouble could not be determined, but may have been an endocarditis or aortitis. One of us (C. C. S.) had seen him several times off and on because of minor complaints for the previous 4 or 5 years. At no time within this period was there any evidence of cardiovascular disease or hypertension. The blood Wassermann reaction was negative, and there were no clinical signs or symptoms of syphilis.

The patient was given a perle of amyl nitrite by inhalation and a 1/150-gr. tablet of nitroglycerin under the tongue. Since this produced no relief, 1/4 gr. of morphine and 1/100 gr. of atropine were given hypodermically. While the patient was waiting for the ambulance, the pain and shock increased to an alarming degree, and he was therefore given another 1/4 gr. of morphine by mouth, but with little effect.

The patient was admitted to the Rockingham Hospital within less than 1/2 hour after the onset of the attack, with a tentative diagnosis of coronary thrombosis. His

condition appeared to be very critical. The unbearable pain in the chest, back, and right upper quadrant still continued, and there was marked cyanosis of the lips and fingernails. The pulse rate was then found to be 56, and the blood pressure 222/70. The patient received 20 cc. of aminophylline solution intravenously, which brought the pulse rate up to 72 but did not relieve the precordial pain.

FIGURE 1. X-Ray Film of Chest.

*This film, taken with a portable machine on the first day of the disease, shows definite widening of the aortic arch in the region of the transverse and descending aorta.*

He was therefore given another 1/4 gr. of morphine hypodermically and placed in an oxygen tent. He did not tolerate the tent well because of restlessness, and it was thought best to administer sufficient morphine to control his suffering. At 1:00 p.m., he received a fourth 1/4-gr. dose of morphine, which was repeated at 2:45 p.m. In other words, 1 1/4 gr. of morphine was necessary within 3 hours to quiet the patient. Nitroglycerin, 1/100 gr., was given under the tongue as often as necessary to obtund his pain. The systolic blood pressure, however, failed to fall below 220. The patient appeared to be too ill to submit to physical examination for several hours.

The admission diagnosis of coronary thrombosis was considered untenable because of the extreme severity and continuance of pain in spite of massive doses of morphine and the nitrites. Moreover, the persistent bradycardia and the hypertension in the presence of pronounced shock were very atypical of coronary thrombosis. Because of the general picture, the likelihood of a dissecting aneurysm of the aorta was suggested by his physician (C. C. S.) and the consultant (H. T. F.). This diagnosis was supported by an electrocardiogram, which was negative except for inversion of T<sub>1</sub> and by a roentgenogram (Fig. 1), which showed a probable dilatation of the descending aorta.

Examination of the blood on admission revealed a red-cell count of 4,620,000 with a hemoglobin of 85 per cent, and a white-cell count of 10,100 with 80 per cent polymorphonuclear leukocytes.

The patient ran a septic type of temperature for the 1st week. During this period he was very critically ill,

## MEDICAL PROGRESS

### CONTROLLING CLINICAL THERAPEUTIC EXPERIMENTS WITH SPECIFIC SERUMS\*

With Particular Reference to Antipneumococcus Serums

MAXWELL FINLAND, M.D.†

BOSTON

THE title of this paper might lead the reader to expect a scholarly dissertation including a historical review of attempts to control therapeutic experiments with biologic agents in human beings. Actually, it is the main purpose of this review to recount in an informal but critical manner some ten years of personal experience with attempts to determine the actual value of antipneumococcus serums in the treatment of pneumonia. Earlier data bearing directly on this problem were not very extensive and were quite inconclusive. Even when one turned away from pneumonia to other infectious diseases in which serums had been used, one could gain little either from the evaluation of the methods used or from the results obtained. At that time, there were at least three important diseases for which specific serums were available and had been used on a large scale with some attempt to control the results.

#### DIPHTHERIA

Perhaps the most successful therapeutic serum, and the one that has become definitely established as effective, is diphtheria antitoxin. This agent was introduced in 1890 by Behring, and was first widely used in human beings following the preparation of antitoxin in horses by Roux and Martin in 1894. It has been used in England and in the United States since 1895, and one of the first places where it was introduced successfully in this country was at the South Department of the Boston City Hospital. There is little question of the efficacy of antitoxin in neutralizing the lethal toxin of the diphtheria bacillus in animals. Efficient methods of preparing and titrating this antitoxin soon became available, and refinements of these methods were made as time went on. When one reviews the available data in an attempt to determine whether the use of this agent is actually effective in reducing the mortality from diphtheria, one is confronted with "a great body

of evidence that can be adduced in favor of the treatment . . . much of which can be interpreted in other ways."<sup>1</sup> For example, from previous experience, there is reason to believe that the severity of the disease is cyclic. Much has been acquired in the form of education in the recognition and early treatment of the disease. Hospitalization is more frequent, with accompanying improvement in general care. There have been improvements in general hygiene and diet that have perhaps increased individual resistance to infections. Much has been learned concerning the care of the patient with laryngeal diphtheria in the way of intubation, and reduction in mortality from tracheotomies probably resulted. The relative significance of these factors in reducing the mortality from diphtheria is hard to evaluate.

In 1923, Andrewes,<sup>1</sup> in a review for the Medical Research Council in England, summarized the evidence up to that time in two categories, one of which he termed "evidence of first rate value" and the other "evidence of secondary value." Some of the data in these categories are worth considering.

Unfortunately, only two therapeutic experiments could be classified as evidence of first rate value. One was that of Fibiger,<sup>2</sup> in Copenhagen, the report of which was published in 1898. This worker treated all cases admitted to the diphtheria wards on one day with serum, and those admitted on alternate days were treated without serum. There were, of course, some cases in which the diagnosis was never definitely established. If these cases are excluded, there were 239 cases treated with antitoxin, with 8 deaths, or a 3.3 per cent mortality, as compared with 245 patients treated without antitoxin, among whom there were 30 deaths, or a mortality of 12.2 per cent. There can be little criticism of this type of alternation of cases, since it is extremely unlikely that on the 'treated' days one would have a group of severe cases and on the 'untreated' days a milder group, or that any other factors might enter into consideration that would detract from the value of the data presented. The total number of cases was rather small. I hesitate in this discussion to

proper controls. In Flexner's accumulated data, there was a mortality of 31 per cent after the exclusion of all cases in which deaths occurred within twenty-four hours, all chronic cases and all patients who were moribund when first treated or in whom there were mixed or intercurrent infections. This figure was compared with the mortality in untreated cases, from which no exclusions were made and which varied from 42 to 80 per cent, averaging 70 per cent. In the treated cases, the efficacy of therapy was shown to vary with the time at which it was administered. It was most effective if given within the first three days of the disease. Cases treated during this time had a mortality of 18 per cent, those treated from the fourth to the seventh day had a mortality of 27 per cent, and those treated after the seventh day, 37 per cent. Flexner also showed a relation to age, with the highest mortality in the group under one year of age and the lowest mortality in the group between five and ten years. Clinically, the most rapid recovery occurred in the favorable age group, and there were fewer complications among the treated cases.

Dopter<sup>12</sup> summarized the French cases treated with serum from the Pasteur Institute. In his series, there was a mortality of 14.5 per cent before exclusion of the moribund cases and those complicated with other infections, and 11.7 per cent after such cases were excluded. In cases treated without serum, the mortality during the same period was 65 per cent.

Experiences with antimeningococcus serums first brought out the importance of type specificity. Specific types of meningococcus were recognized and classified in 1909 more or less simultaneously by three different workers. Hine,<sup>13</sup> in reviewing the results of serotherapy in some of the British forces during World War I, showed that the treatment was highly effective in Type 1 and Type 3 cases, and was much less satisfactory in Type 2 cases, but the number of cases was small. In his first series, there were 90 cases, 34 of which were Type 1, with 1 fatality; 10 were Type 3, and all these patients survived; and there were 7 deaths among 32 Type 2 cases. He emphasized the value of early treatment, daily doses, prompt typing, adequate use of the appropriate serum and the administration of large doses for Type 2 cases. These arguments have become commonplace, since the various therapeutic experiments with antipneumococcus serums emphasized the significance of each of these points. In a second series, including moribund patients but excluding those with intercurrent diseases, there were 141 cases, with 19 per cent deaths among those treated within

the first six days. There were 65 cases with 9 per cent deaths among patients with Type 1 infections, 39 per cent among 104 with Type 2, and 25 per cent among 28 with Type 3. Unfortunately, an epidemic of influenza intervened at the time of the second series, so that part of the mortality may have been due to that cause. There were 48 untyped cases in this series, with a mortality of 45 per cent.

Numerous reports concerning the use of antimeningococcus serum have appeared since the early studies of Flexner and Dopfer. Not all have been quite so favorable. One carefully controlled study carried out in Detroit by Gordon<sup>14</sup> shows how any one group of figures collected over a limited period might be misleading. In his report before the Association for Research in Nervous and Mental Diseases in 1931, Gordon tabulated the mortality from meningococcal meningitis in the Detroit area and from the Herman Kiefer Hospital for the years 1922 to 1931. All the cases during this period were treated with serum. The mortality in the endemic years 1922 and 1923 was 65 and 55 per cent, respectively. In the pre-epidemic years 1924, 1925 and 1926, the mortality was 19, 14 and 41 per cent, respectively. In 1927, there began an epidemic that reached its peak in 1929 and subsided in 1931. During this period, the mortality rose sharply to a peak of 65 per cent, and then dropped to 42 per cent. For the most part, only one type (Type 3) was found to be the causative agent. The serum at first was polyvalent with a low titer for Type 3, but was later monovalent and of high titer. The results indicate clearly either that the efficacy of antimeningococcus serum was misjudged or that other factors were introduced which militated against the best results. One point might be mentioned that has been illustrated in the low figures of 19 and 14 per cent, which Gordon reported for the endemic years 1924 and 1925, namely, in some endemic periods the mortality may be low, or during such periods good serums may be available against the particular strain that causes the infection. This feature is also brought out in the striking results that Tillett and Brown<sup>15</sup> reported from Johns Hopkins Hospital during the spring of 1935, when they had only 1 death among 25 consecutive treated cases.

Tillett and Brown's results, although not conclusive, may hold the answer to another secret concerning mortality, which has been perhaps more clearly revealed in the use of antipneumococcus serums. They employed serums prepared in the New York State Laboratory. These serums were of uniform quality and of high potency against the particular type with which they were

concerned. Although their cases were not typed, the strains subjected to serologic classification all fell either into Group 1 or into what they called Group 1-3. The serums included both concentrated and unconcentrated lots, but all of them contained high titers of antibodies (by the various laboratory criteria used) against the particular type that occurred in this series. They also used larger doses of serum, and this may have been an important factor in the low mortality.

In determining the value of antimeningococcus serum, one is thus left with a peculiar impression similar to that following the early use of antipneumococcus serums, namely, that one is dealing with an agent that is apparently effective, but conclusive proof of its effectiveness is lacking. Most of those who used the serums noted the rapid clinical improvement in the patients who responded; the best results occurred in the cases treated early and in the young patients, except infants. Nevertheless, considerable conflicting data concerning mortality in different communities, and at different times in the same community, leave an element of doubt concerning what relation the drop in mortality ascribed to the use of serum actually has had to the variations in the disease at a particular time and place. The use of antimeningococcus serums is already involved by many of the same problems that later confronted workers concerned with the treatment of pneumonia: type variations, differences in mortality among the types and in different age groups, variations in the potency of serums and difficulty in estimating such potency by laboratory tests, the results of which have any correlation with clinical efficiency.

#### ANTERIOR POLIOMYELITIS

The problem of evaluating the use of convalescent serum in the treatment of anterior poliomyelitis presents an even more complex situation. In the first place, there is involved a serum that experimentally has been shown to have only what have been called "neutralizing antibodies."<sup>16</sup> There is no evidence that convalescent serums or antisera prepared against the virus in experimental animals are of any value in curing disease or in preventing paralysis even in animals, once the infection has taken hold. It is obvious that human beings cannot be treated at the same time that the virus is introduced. Therefore, theoretically, convalescent serum has no standing as a therapeutic agent, even on an experimental basis. Nevertheless, it has been accepted widely. It was only after attempts had been made to reinvestigate the problem by carefully controlling the results that any

element of doubt concerning the value of the serum was introduced.

In this disease, the mortality has shown wide variations in different epidemics, and even within the same epidemic in different communities. Similar variations in extent and severity of the paralysis have occurred during the same epidemic. Comparisons between cases that were serum treated and those that were not have been most difficult. One is dealing with a therapeutic agent accepted more or less on faith and used because in this disease no other effective therapy is available. The results, as reported, have been accepted without criticism. In 1932, Kramer and his associates<sup>17</sup> presented the results of their experiments in Brooklyn, and Park,<sup>18</sup> at the Association of American Physicians, presented the results of a large experiment undertaken jointly by the New York City Department of Health and the New York Academy of Medicine. These studies indicated that in two large contemporary series of cases the mortality and the extent of paralysis were almost identical, and, in fact, that the differences observed were slightly unfavorable for the serum-treated cases. The results were disbelieved by some workers and merely ignored by others,\* but they have since been confirmed.<sup>19</sup>

#### PNEUMOCOCCAL PNEUMONIA

Before turning to the immediate problem concerning pneumonia, one should consider some of the factors that are involved in determining the therapeutic efficacy of an antiserum for human patients after its beneficial effects in experimental animals have been clearly demonstrated. The chief factors may be listed as follows: the problem of diagnosis, including both the clinical and the etiologic diagnosis; the factors in the parasite or the invader; the factors in the host; the factors concerning the antiserum; the extent to which the host and the invader have interacted at the time when the antibody is administered; and the complications of the infection.

In diphtheria, the diagnostic problems are not very difficult. Treatment usually can be administered on the basis of clinical diagnosis, and the etiologic diagnosis is not too difficult to establish or to verify. The host is usually a young person, and complicating conditions in the host are not important factors. In infants, the prognosis is poor, as in most other severe infections, and

\*Here again, one observes the mixed motives that sometimes confront the laboratory scientist when he is concerned with clinical experimentation. In discussing Park's paper, Flexner<sup>19</sup> stated "There is a consensus . . . that the use of convalescent serum does no harm. Since it cannot be affirmed that in an individual case it does no good, should its use be withheld? This is a question to be answered not by a pathologist but by a practitioner." Many a budding clinician hoping to bring a strict "scientific attitude" to bear on some of his bedside problems felt a bit dismayed by these remarks.

specific serum therapy is least effective. The infecting organism in diphtheria was formerly thought to be uniform in its virulence and toxin production, but it is now recognized that both these factors may vary, as already noted. This factor is the most significant in considering the value of previous reports on this disease. Standardization of the antibody has been fairly well established. Antitoxin is comparatively uniform in quality, at least within the range necessary for therapy. Even on this point, however, there is now some doubt, since the relation between the antibodies produced by toxin from the various types of diphtheria bacilli cannot be evaluated properly at the moment. It is recognized in diphtheria, as in other diseases, that the earlier the treatment is undertaken the better the results. This is corroborated by fairly reliable data. Most reports that deal with numbers large enough to be of value, however, indicate that antitoxin has a definite effect at any stage of the disease. The reason why the results of the therapy of diphtheria in certain recent epidemics have been less favorable than in the past is now ascribed to the occurrence of the gravis organisms. The effectiveness of antitoxin against infections with this type will have to be re-evaluated. Complications of the infection itself are related directly to the action of the toxin, or to mechanical complications in laryngeal involvement. The incidence of laryngeal diphtheria and the methods by which this form of the disease is handled, aside from the specific antitoxin, are also major factors in the fatality rates in the serum-treated cases.

The diagnosis of meningitis is usually not difficult, especially in epidemics. The host factors are not much more disturbing in this disease than in diphtheria. The problems concerning the invader are important, since the mortality from different types varies considerably, and since the efficacy of the serums against each type is apparently also quite variable, being most effective against the Type 1 and least effective against the Type 2. The antibody presents difficulties in standardization that have not yet been entirely overcome. The use of in vitro tests, such as the agglutination, complement-fixation and precipitation tests, has not always paralleled the results of protection tests, which are difficult to standardize. The stage of the disease when treatment is begun presents the same problem as that of diphtheria. The complicating factors in the treatment of meningitis are such as may interfere with the efficiency of treatment; for example, the development of spinal-fluid block or the deposit of thick layers of fibrin that enclose collections of purulent material not amenable to drainage. These

complications may maintain the organisms locally after the general infection has been overcome.

In poliomyelitis, the diagnostic problems are difficult to evaluate, particularly since they have been complicated with the question of so called "paralytic poliomyelitis." The etiologic diagnoses are made essentially on clinical grounds and cannot at present be established. The hosts are usually young. The problem of variations in virulence of the invader is recognized but not understood. The serums are practically impossible to standardize at the present time, so that the entire choice of specific therapy in poliomyelitis rests on rather precarious grounds, as demonstrated in the most recent therapeutic experiments.

At the time when the attempts to evaluate serum therapy in pneumonia were first made in a serious manner at the Boston City Hospital,<sup>29</sup> there were difficulties on all scores. Some of these problems have since been solved, but most of them still remain. Since treatment was then limited to cases of typical lobar pneumonia, the clinical diagnosis was relatively simple. Etiologic diagnosis was complicated by the fact that treatment required type-specific antibody, at least so far as could be ascertained from animal experiments. Type diagnosis was then still a time-consuming matter. There was, in addition, the difficulty of determining the etiologic relation to the disease of any pneumococcus type found in the sputum, since that was the main source of material for typing. The occurrence of bacteremia in any given case usually solved the problem of the etiology for the particular patient concerned. Even this fact, however, frequently became known only some time after a type diagnosis had been made from the sputum. There was also the factor of mixed infections, since it is rare to obtain pure cultures of pneumococci from sputum, particularly in the early stages of the disease when serum might be expected to be most effective. Host factors in pneumonia were obviously of the greatest consequence, particularly in large municipal hospitals, where a great number of the patients are in old age groups and suffer from degenerative diseases. Many of the patients of all ages may be affected to some degree by nutritional disturbances, and a great many adults suffer from chronic alcoholism. With respect to the parasite, there was of course the problem of specific types of pneumococci already mentioned. In addition, the possibility that the virulence might vary from year to year, even with the same type, was a factor. The extent to which the host and the invader have interacted at the time that specific treatment is begun is, of course, most significant

1 cases of pneumonia. This became clear from the very start when the attempt was made to treat patients regardless of how long they had been sick.<sup>20</sup>

The antibody itself presented more than its share of difficulties. Part of the problem later on concerned the evaluation of the toxicity of various lots of serum. It was soon recognized that serum reactions were entirely independent of antibody content and interfered considerably with the therapeutic end results. In fact, these untoward reactions often made it impossible to use some lots of serum. The methods of refining and concentrating antibody were being developed at the same time, and considerable controversy was aroused among some workers about the relative antibody content and therapeutic value of concentrated and unconcentrated serums. The controversy hinged on the procedures used in evaluating potency, which until recently depended solely on the mouse-protection test.

Complications from pneumonia may, of course, in themselves be fatal, even after the acute disease in the lung has subsided. They are recognized as occurring in the severest cases and in those in which invasion of the blood stream has occurred, but they usually appear late in the disease. Thus, the question of delayed therapy is intimately related to that of complications.

All the early studies were carried out with horse serums. Antibodies of high titer were attained in horses with great regularity against Type 1 pneumococci, but Type 2 antibodies were difficult to produce in high titer, and different horses varied considerably in this respect. The Type 3 pneumococcus presented a hopeless problem, since significant amounts of antibody for this type could not be produced. After the newer classification of pneumococci became established, it was recognized that some of the new types, which were most prevalent, were highly antigenic in horses, and good titers against them were regularly obtained. Notable among these was Type 5. More recently, it has become possible to produce in rabbits highly potent therapeutic serums against all types of pneumococci.

At the Boston City Hospital, there had been two clinical experiments in the serum therapy of pneumonia before Sutliff and I began our studies. The first was that of Locke and the workers on the Pneumonia Service, which was organized during the great influenza epidemic and continued through the year 1922. Locke<sup>20</sup> attempted to carry out a very carefully controlled study with the Type 1 serum prepared in the Massa-

chusetts Antitoxin and Vaccine Laboratory according to the methods developed at the Rockefeller Institute. The results at the Rockefeller Institute, as well as those in other clinics, were not very convincing. There were no controls. Locke, during the first year of his study, treated all Type 1 cases, and during the subsequent two years treated a strictly alternated series of Type 1 cases. The final result in groups of about 70 cases each showed an almost identical mortality in the first year, when all Type 1 cases were treated, and in the second year, both in the treated cases and in the alternate control cases. The only indication that there might be some curative value in the serum that he employed appeared from the results of the 12 treated cases in which the serum was given before the end of the third day of illness. None of these patients died. Locke was dealing with unconcentrated serums, whose potency may have been extremely low, as later shown by Felton and Stahl<sup>21</sup> in their survey of the problems of standardization.

It is interesting that the mortality from Type 1 pneumonia in each of Locke's three series was about 17 per cent. A more careful survey of these cases shows that during the first period there was but a 17 per cent incidence of bacteremia, and that during the second period, the treated cases had a bacteremic incidence of 44 per cent, as compared with 22 per cent among the controls. All the studies in both treated and untreated cases during the last ten years have indicated that the mortality is directly proportional to the bacteremic incidence. In untreated cases, except in those due to Type 3 pneumococcus, which are almost invariably fatal if the blood is invaded, the bacteremic incidence practically tells the mortality in any group of cases.<sup>22</sup>

Following Locke's study and beginning in the year 1924, the Department of Preventive Medicine and Hygiene of the Harvard Medical School became interested in a therapeutic experiment at the Boston City Hospital. In this study, alternate cases were treated with various lots of serum, which Felton had prepared by various methods of concentration. The study was conducted by a single resident, who was under the general direction of Felton, and had the clinical supervision of Locke and Robey. This resident obtained sputum for typing and treated alternate cases that were called to his attention in which a definite clinical diagnosis of pneumonia was made. The records of both treated and control cases were turned in to Felton. There was a different resident each year, and when I undertook the studies there had been five years of this experiment. From

the records available for these years, an attempt was made to analyze the results of the serum therapy. Utilizing the experience of Locke and also considering that the experiment was done with bivalent serum containing Type 1 and Type 2 antibody, we attempted to learn: whether the serum therapy produced a reduction in mortality; whether the reduction was greater in the cases due to Types 1 and 2 pneumococci than in the others; and whether the patients treated early in the disease were benefited more than those treated late. It was also of interest to learn whether this rather impersonal method of handling a therapeutic experiment resulted in reliable and comparable groups of treated and controlled cases.

The mortality figures<sup>23</sup> showed that the cases of Type 1 and Type 2 pneumonia treated within the first three days of the disease had a definitely lower mortality than the untreated cases, or than the cases treated on the fourth day or later. The disturbing feature was an apparent reduction in total mortality in the Type 3 and so-called "Group 4" cases. These patients had received the bivalent (Types 1 and 2) serums, which contained no specific antibody for the types with which they were presumably infected.

It was assumed that the successive residents treated alternate cases as long as they had serum, discontinued their experiments when no serum was available, and kept records only during the time that the experiment was going on. It was of some interest, therefore, to find out to what extent two important factors might have influenced the choice of cases: one was the stage of the disease, and the other was the age. In other words, it was essential to determine whether a larger proportion of the younger patients and more of the patients admitted early in the disease might have been treated with serum to account for the differences in mortality in the serum-treated Types 3 and 4 cases. It has been well recognized that mortality in pneumonia, regardless of the etiologic agent, increases with advancing age. If a larger number of old people were included in any groups, obviously the gross mortality figures would be influenced unfavorably. On analyzing the data on this point, it was easily shown that the so-called "control cases" had a definitely unfavorable age distribution. This was also true of the distribution according to the stage of the disease. Among the serum-treated cases, a larger percentage were admitted early in the disease, and fewer late cases were included. To offset this factor and at the same time to obtain some idea of the effect of serum on the course of the disease, it was necessary to compare the total duration of the acute disease in

the Type 1 and Type 2 treated cases with that of similar patients who were not treated with serum and who were admitted to the hospital at the same stage of the disease. This was done by comparing the average total duration of the acute disease (using arbitrary but similar criteria) with the duration of the illness at the time of admission to the hospital. In this way, it was shown that the duration of acute illness was shortened in Types 1 and 2 cases by early serum treatment. Also, among the Type 1 cases, composite temperature charts were constructed for the patients who recovered without complications, one for those treated with serum, and another for those who were not treated with serum. When these composite temperature charts were constructed so that they began with the first day in the hospital, differences between the treated and the untreated groups were not apparent. However, a rearrangement of the data according to the day of onset of the disease showed a definite reduction in the total period of febrile illness among the Type 1 treated patients who recovered.<sup>23</sup>

When, in 1929, Sutliff and I attempted to formulate further plans for the evaluation of serum therapy, it became obvious that it would not be possible, within a period short of several years, to produce reliable and significant evidence on the basis of mortality figures. We therefore attempted to use the results in individual cases as a basis for comparison, following treated and untreated cases very carefully and alternating serum therapy by a strict method, which was controlled entirely in the laboratory. Serum was given to alternate cases of each type as soon as the type was determined. From the very start it became obvious that such controls were only self-deluding. We were confronted with patients in whom the type was determined after the patient was already dead, and others who were moribund when the results of the typing became known. We soon limited our experiments to those patients who, at the time the type was determined, were ill for four days or less. This, in addition to the fact that an ample supply of highly potent Type 2 antibody was available, made it possible to include both Type 1 and Type 2 cases in such an experiment.

The results from the point of view of mortality are difficult to evaluate because the numbers were small. The clinical effects of serum were determined by using the temperature and general symptoms as criteria. The results in Type 1 cases during the first year were thus tabulated. By all recognized criteria for clinical recovery, the termination of the disease in serum-treated cases was shown to be in relation to the time when the

type was determined, and thus to the time when the serum treatment was given. This was demonstrated clearly in this first year's experience, in which all Type 1 cases were included, regardless of the time of admission.<sup>24</sup> Similar results were demonstrated, even more clearly in the cases of Type 1 pneumonia, both treated and untreated, during the next three years.<sup>25</sup> The duration of acute symptoms was always relatively short in treated cases, and comparatively long in untreated cases. Symptoms of the acute disease rarely persisted beyond the fourth day in the patients admitted early and treated with serum, and rarely ended before the fourth day in those who were not treated with specific serum. Similar results were also demonstrated in Type 2 cases.<sup>26</sup>

During the time when only Type 1 and Type 2 serums were available, we tried to obtain as many data as possible on all other cases of pneumonia, from both the clinical and etiologic points of view. We attempted to type all cases in which pneumonia was suspected, followed them, and eventually analyzed the results with the hope of having a background for comparison when new serums or other remedies became available. A survey of these cases, as well as of those that were treated, showed certain constant features with regard to mortality: bacteremic patients always had a much higher mortality than corresponding patients without bacteremia; the mortality increased with advancing age; in serum-treated cases, there was a general correlation between the time of treatment and mortality,—the earlier in the disease treatment was begun the lower was the death rate; the greater the extent of the pulmonary lesion at the time when the patient was admitted to the hospital or when treatment was begun, the higher was the mortality; the development of infected focal complications increased the death rate; the occurrence of underlying acute or chronic disease had a marked influence in increasing the death rate in both treated and untreated cases.

As time went on and better serums became available for Type 1 and Type 2 cases, as well as for other types, it became clear that we were concerned as much with the problem of the conditions under which these serums were useful in reducing mortality or in cutting short the disease as we were in the general reduction in death rate.

During the early experiments with the serum treatment of pneumonia, as already mentioned, alternate patients were given the bivalent serum before the type determination was made. At that time, one feature of the effects of serum treatment was more impressive than any other. When a

patient who had been ill for four days or less was admitted to the hospital and given serum, if he was well the next morning, the type was almost always found later to be either Type 1 or Type 2. This seemed to us at the time to be the best clinical evidence for the effectiveness and specificity of the serum, in spite of the fact that this was difficult to express in a convincing form, except by comparing the clinical course of the disease in treated and untreated cases in the manner already mentioned. However, when a larger body of data became available, which was sufficient to be analyzed into the factors that I have already outlined, the mortality figures also appeared to be significant and convincing. The available figures are illustrated in the reports<sup>27</sup> on the results of treatment in Types 1, 2, 5 and 7 cases during the nine-year period from 1929 to 1938.

The outstanding features of these mortality figures are: an increasing proportion of cases were submitted to serum therapy; a constantly low mortality was observed in those treated with serum; and a constantly high mortality was noted in patients who escaped serum therapy for one reason or another—many of the patients who escaped serum therapy in the latter years were diagnosed either after recovery or at autopsy.

In addition to the gross fatality rates, a large amount of clinical evidence based on the following facts has been gathered: there is a definite relation between treatment and recovery; bacteremia is arrested following serum therapy; the spread of the disease in the lung is arrested following serum administration; except in those treated very late in the disease, the mortality in serum-treated cases is always lower than in comparable cases not treated with serum—this is true in all age groups, in bacteremic and nonbacteremic cases, in those with limited or extensive lung involvement, and in those with and without complications or other predisposing conditions; and the beneficial results of serum therapy are strictly type specific.

Another important feature in the evaluation of the therapy has been the fact that in all but a very few cases, failures to obtain striking beneficial results following serum administration could be traced to certain well-defined causes. These are, briefly: delayed treatment; inadequate therapy or improper treatment in the sense of spreading dosage over a long period—the use of serums of low potency falls in this category; misdiagnosis, that is, etiologic misdiagnosis, which includes errors in typing and the improper evaluation of the relation of the bacteriologic finding to the etiology of the disease; the presence of focal

complications, notably empyema, at the time treatment is begun; and the pre-existence of severe systemic disease such as cardiac or renal failure, cerebrovascular accidents and alcoholic delirium. How or why these factors interfere with the results of therapy is not within the scope of this presentation. It is obvious that many of these conditions, which are unfavorable from the point of view of specific serum therapy, may nevertheless be influenced favorably by other types of treatment, as we have seen since the introduction of chemotherapy.

If an attempt is made to summarize our experience in pneumonia in relation to the experiences of others with various infectious diseases, we find that the actual attempts to demonstrate reductions in mortality by carefully controlled clinical experiments were not entirely successful and were essentially abandoned in favor of the careful observation of individual cases for the beneficial effects of serum or for the causes of the failure to obtain such beneficial effects. We were led to the belief that therapeutic antipneumococcus serum, if it were effective, should demonstrate its benefits in every case in which it is used unless definite and recognizable factors are present that militate against its efficacy.

In conclusion, it is probably safe to say that in the evaluation of treatment in a disease like pneumonia one must rely on the integrity of the reporter to present all the relevant facts. Only when all the details are presented is it possible to demonstrate the efficiency of the agent in question. The differences between treated and untreated cases must be unequivocal and must be consistent. Only in this manner can the reporter himself be really convinced of the significance of his results. The reader of his reports can become satisfied only when he goes through similar experiences and is likewise impressed with successive individual results.

The relation of serum therapy to chemotherapy is not strictly within the scope of this paper. However, since this is now the only problem of importance with respect to the use of serum in pneumonia, it will be considered briefly.

It is generally conceded that chemotherapy with one of the sulfonamide drugs, notably sulfapyridine or sulfathiazole, is now the treatment of choice in cases of pneumonia.\* The question arises whether the use of specific serum in addition to one of these effective sulfonamides is more beneficial than the treatment with that drug alone. From what has already been said concerning the evaluation of antipneumococcus serums, it is ob-

vious that this question is considerably more difficult to answer decisively on the basis of strictly controlled clinical studies.

Since adequate data have been brought forth to attest the efficacy of the sulfonamides, it is no longer possible to deny any patient with pneumonia the benefits of their use. Even a delay in the application of chemotherapy is justly open to criticism because with these drugs, as with other remedies, early treatment is essential for the best results. Furthermore, the ease of administering the drugs and the frequency and rapidity with which the pneumonias respond to their use make additional therapy useful, at best, only in selected cases that do not yield readily to the drugs alone. It is difficult to see how a clinical experiment that takes these factors into account can yield a decisive answer to the question at hand.

In the cases treated at the Boston City Hospital,<sup>29</sup> an attempt was made to compare the results of treatment with serum and sulfapyridine used separately and in combination, to determine the conditions under which each type of therapy might be most advantageous. The combined therapy was used in the severest cases, and in patients who did not seem to improve under treatment with one or the other agent when used separately. A large proportion of the cases in which the combination of serum and drug was used may, therefore, be classed as failures, or threatened failures, from chemotherapy. Similar data have been reported from most of the other clinics in which such studies have been undertaken. Obviously, no conclusions can be drawn from such data concerning the relative merits of the drug alone and of the combined therapy. Our results suggest that in most of the cases with the worst prognosis, the use of serum in addition to sulfapyridine may increase the chances of recovery and may shorten the duration of the acute illness in patients who survive. The results in individual cases, although they generally support this view, still leave room for doubts.<sup>30</sup>

In two recent reports, the attempt has been made to cope with this problem by setting up strict criteria for the choice and alternation of cases. Dowling, Abernethy and Hartman<sup>31</sup> alternated their cases within each type of pneumococcus as soon as the type was determined, one case being given sulfapyridine alone and the next receiving both this drug and serum. To avoid too great a delay in initiating therapy, every patient in whom the pneumococcal type was not obtained within six hours was excluded from the study and given sulfapyridine. In the patients who received the combined therapy, recovery was more rapid than in

\*The relevant literature on this subject has recently been summarized.<sup>32</sup>

ose treated with the drug alone, as judged by average duration of fever. In the patients over 40 years of age, the mortality was also lower with the combined treatment. The only serious objection to this study is the small number of cases involved.

In the second report, by Plummer and his associates,<sup>3</sup> all patients were treated with some sulfonamide drug as soon as the clinical diagnosis was made, and alternate cases within each type were placed in the series treated by serum in addition to the drug. Some of the patients were already dead and others were afebrile at the time the type was determined; they received no serum, but were nevertheless retained in the group receiving combined treatment. From a comparison of the death rates and of composite temperature curves, these authors concluded that there was no significant difference in the results of treatment in the two series.

It is rather odd, in view of the strict alternation of types stressed by these authors, that for many of the types there is a preponderance of cases either in the series treated with the drug alone or in the combined therapy series. The length of the delay before serum treatment was given in most cases is not mentioned, but in some of the cases it was as long as twenty-four hours. Furthermore, although mention is made of the number of patients who received serum and died within twenty-four hours, the total number of patients who actually received serum is not given. Moreover, a considerable portion of the mortality among the patients who received combined treatment occurred within twenty-four hours of admission to the hospital, whereas only a small number of those receiving the drug alone died within twenty-four hours of entry. Although it is possible to deduce from these data that some of the fatalities were the result of the serum therapy, it seems much more probable that some unconscious selection on the part of the authors played an important role in the inclusion of the poorest subjects among the serum recipients. This is only a natural occurrence, since there is always a tendency to give to the patients who seem the most severely ill the benefits of any remedy that is known to be effective. It is likewise natural, particularly in view of the time and effort required for serum administration, to avoid giving this type of therapy to patients who seem to be improving adequately without it.

The conclusions drawn by these authors may or may not prove to be correct, but one cannot help believing that the results as presented are

not only inconclusive but even grossly misleading. It would likewise be erroneous to draw any conclusions regarding the relative merits of these two types of treatment from mortality figures obtained from reports in which the selection of cases was not strictly controlled. This is true of groups of cases from a single clinic, such as those I have presented,<sup>29</sup> but it is all the more true of cases gathered by central agencies from the reports of scattered physicians.

The two studies that have been discussed concerned adults. Another controlled study, carried out in infants and children, was reported by Carey.<sup>33</sup> He alternated his cases as soon as the diagnosis of pneumonia was made and the pneumococcus typing was completed. In cases in which the causative organism was found to be a pneumococcus for which specific antipneumococcus serum was available, alternate patients who were not serum sensitive received serum in addition to the drug. This alternation was not followed strictly because of certain patients in whom either typing was delayed or a mixed infection was present, and it was not immediately clear which was the causative type. In such cases, chemotherapy was started, and the patients were frequently well when the question of serum therapy arose. The fatality rates in all groups of cases were so low that comparisons were not justified.

The average duration of the disease was compared and was of some interest. It was found that the duration in the treated cases was the same after sulfapyridine as it was after sulfathiazole. The outstanding finding in this series, however, was that the average duration of the pneumonia after treatment was appreciably shorter in those patients who received specific antipneumococcus serum in addition to sulfapyridine or sulfathiazole, as compared with the duration of the acute illness after treatment with sulfapyridine or sulfathiazole alone.

The question whether the use of serum in addition to a sulfonamide is superior to the use of the drugs alone thus remains unanswered. It is my opinion that this particular question as it concerns pneumonia is now a highly academic one, since it is unlikely that any physician would contemplate using the combined therapy as a routine in all cases. It seems far more important to concentrate on the failures of chemotherapy and attempt to determine, first, whether such failures can be predicted, and then which of them can be averted by the use of serum. Even this is not a simple task. Fortunately for the patient with pneumonia, however, the failures from chemiotherapy are few.

A reply by Dr. Plummer to the author is published in the issue of the Journal (page 51).

## CASE 27391

## PRESENTATION OF CASE

A thirty-seven-year-old man entered the hospital complaining of fatigue, hemoptysis and pain in the left arm.

Two years before admission, the patient noticed that he was becoming unduly fatigued, and that rest gave him no relief. He carried on until eight months before admission, when a small hemoptysis—about one teaspoonful—occurred, without other symptoms referable to the respiratory system. A chest plate was taken immediately, and a diagnosis of tuberculosis of the left apex made; the patient was sent to a sanatorium, where intensive studies were carried out, including x-ray films, fluoroscopy, lipiodol injection, bronchoscopy, a punch biopsy of the lung and sputum examinations. The patient was told that tuberculosis was definitely ruled out and that the most likely diagnosis was a low-grade infection of the lung, possibly due to a fungus. With sanatorium care and potassium iodide treatment, he improved and was able to return to work at the end of four months.

Eight weeks before admission, fatigue returned, and a dull gnawing ache developed in the left anterior chest. In addition, along the inner surface of the left arm immediately below the axilla, he noticed pain that gradually spread down the lateral surface of the arm as far as the mid-forearm. Both pains increased in severity, the arm pain becoming the more pronounced of the two. Six weeks before admission marked the onset of night sweats, which were still a symptom at the time of admission. Two weeks before entry, the patient went to Florida, but after several days developed a fever rising to 102°F. He entered a hospital, and the fever subsided within a few days; x-ray films were taken, and he was referred to this hospital. There had been a loss of 10 pounds in weight in the previous eight months. Cough and sputum were never very marked symptoms, the latter being limited to a half teaspoonful a day, raised in the morning and perhaps once again during the day. It consisted of brown purulent material.

On examination, the patient was well developed and well nourished and not in apparent distress.

Examination of the heart was negative; the blood pressure was 130 systolic, 70 diastolic. In the upper left chest, from the supraclavicular fossa down to the third rib anteriorly and the fourth thoracic vertebra posteriorly, there was dullness to percussion, with diminished tactile fremitus and breath sounds, but no rales. The abdomen was normal except for a small right inguinal hernia.

The temperature was 99°F., the pulse 100, and the respirations 22.

Examination of the urine was negative. Examination of the blood showed a red-cell count of 4,330,000 with a hemoglobin of 13.6 gm. (photoelectric-cell technic), and a white-cell count of 8900 with 82 per cent polymorphonuclears. The nonprotein nitrogen of the blood serum was 28 mg. and the protein 6 to 7 gm. per 100 cc.; the blood Hinton reaction was negative. Repeated examinations of the sputum were negative for tubercle bacilli and actinomyces; cultures yielded rare colonies of beta hemolytic streptococci, with a predominance of alpha hemolytic streptococci.

An x-ray film of the chest showed an area of dullness occupying the upper portion of the left lung field. In films taken in the usual manner, the shadow appeared to be of homogeneous density and extended from the extreme apex to the third rib in front; the trachea and mediastinal contents were not displaced, and the diaphragm on this side was in the usual position and only slightly limited. The lung fields, except for the area described, were normal in appearance. The heart shadow was not increased in size or abnormal in shape, and there was no displacement. In a film taken with the Bucky diaphragm, the lower half of the shadow presented a mottled appearance, with dense lines running through it suggesting the walls of bronchi or trabeculation. The margins of the shadow were quite dense, and the lower border was convex. In the lateral view, the shadow appeared to extend from the anterior to the posterior wall, and its greatest extent was in the middle part of the chest. The trachea appeared to lie anterior to it; there was no visible pulsation.

A review of films taken in other hospitals showed that a little over two years before admission, the left apex was clear and there was no visible tumor mass. There was, however, some increased radiance in this portion of the lung, suggesting air trapping. Seven months before admission, the mass was about half its size on entry and had a similar structure and appearance. In films taken with the patient lying on his back, in other hospitals and here, a widening of the second interspace in the axillary line was evident.

There was no evidence of a destructive process in the ribs in any of the films, and no visible calcification within the mass.

Each day, the sputum was dark reddish brown, and the patient said it had been exactly similar for the past eight months. The pain in his arm grew worse, and was no longer controlled by aspirin and codeine. On the ninth hospital day, constriction of the left pupil was noticed for the first time. The next day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. THEODORE L. BADGER:<sup>\*</sup> May we see the x-ray films?

DR. AUBREY O. HAMPTON: This first examination was made in 1938, when the chest was considered normal. There might be the slightest variation in density between the lung apices, the left being thought by some observers to be a little more radiant than the right. This next film, which was taken two years and two months later, shows a fairly homogeneous dense shadow occupying the region of the left upper lobe, with perhaps a little mottling. There is no displacement of the trachea and no disease in the ribs. The remainder of the lung fields is clear. Still later films show little or no increase in the total size of the mass, but the mottling has become more prominent and there is a strong suggestion of cavitation. These are laminographic films, and this is the same area seen on the plain film. The inferior margin of the shadow is sharp, and within it there are mottled 1-cm. to 2-cm. areas of rarefaction, which are almost like a cluster of grapes, very regular in size. Another significant finding is an unusually straight bronchus, which looks as though it were being pulled on and runs into the area of disease. It filled irregularly with lipiodol. No lipiodol entered the area of disease, and the trachea and main bronchus were not pressed on. In summary, the film shows a fairly sharply defined shadow continuous with the ribs and the apex of the lung and, in the lower portion, multiple cavities of almost the same size. There is also a straight rather drawn-out looking irregular bronchus.

DR. BADGER: Summarizing briefly this complicated and rather difficult case, the outstanding features of the history are two years of fatigue, and hemoptysis eight months before entry. At that time, a diagnosis of tuberculosis was made, followed by hospitalization, and a careful study, which, so far as I can tell, very definitely ruled out tuberculosis. I have no idea what the final diagnoses on discharge from the sanatorium were,

except that fungous infection was considered. The patient returned to work four months later and remained there for two months, after which he was forced to retire. Eight weeks before admission, he developed a dull aching pain in the left chest; night sweats also appeared. The pain was in the axilla and radiated down to the forearm. The patient had fever and lost 10 pounds in weight.

Examination was negative except for local findings in the upper third of the left chest, with dullness and diminished breath sounds. No rales could be heard.

The blood and laboratory findings were entirely negative. X-ray study showed the findings that have been pointed out. The patient had, in addition, a final appearance of Horner's syndrome. It was not a complete Horner's syndrome, at least according to physical examination, since only the smallness of the pupil on the left side was noted. Nothing is said of lidlag or of enophthalmos, both of which are customarily seen with Horner's syndrome.

Our problem is to decide whether this is infection or tumor, and if it is tumor, whether it is a growth within the lung itself. The recurrence of symptoms eight months before entry, with dull pain in the shoulder, is not characteristic of tuberculosis or of any infection. I am inclined to rule out infection, which if present does not seem to be an important part of the picture, and believe that we are dealing with a tumor mass within the chest.

The pain in the upper left chest, the radiation of pain down the arm and the development of a Horner's syndrome immediately make us wonder whether we are dealing with a Pancoast tumor. Pancoast,<sup>†</sup> in his original description in 1924, reported 4 cases, in 2 of which autopsies were performed. Both were first thought to be epitheliomas but were finally diagnosed as squamous-cell carcinomas. Pancoast defines this particular tumor clinically. It must be an extrapulmonary tumor and must show no evidence of origin from the lung or bronchus. It must present erosion of the bone, in addition to pain in the shoulder and axilla that radiates down the arm, with wasting of the muscles of the hands. In all Pancoast tumors, small shadows in the far apex of the lung are visible by x-ray examination.

We must distinguish between the Pancoast tumor and the Pancoast syndrome, which we know today is caused by tumors other than those he originally described. Pancoast's final analysis was that the tumors that arose outside the

<sup>\*</sup>Instructor in medicine, Harvard Medical School, chief of Thoracic Clinics, Boston City Hospital

<sup>†</sup>Pancoast, H. K.: Importance of careful roentgen ray investigation of apical chest tumors. *J. A. M. A.* 83:1407-1411, 1924

horax, in the superior pulmonary sulcus, originated from embryonic rests of the fifth bronchial left. Other conditions will produce the syndrome. They may be tumors arising in the spinal canal from the meninges, or metastatic lesions in the lymph nodes of the neck. These can be fairly well ruled out in this case. Therefore, I get the impression that we are dealing with an intrathoracic and intrapulmonary tumor, rather than extrapulmonary tumor of the Pancoast type.

If we believe that we are dealing with a tumor within the chest, what is our diagnosis? Is this a benign tumor or a malignant one? The character of the x-ray shadow is certainly suggestive of something with a sharply defined border, which was progressive in size and which was certainly not destructive, so far as the bone was concerned. The tumor mass invaded vital structures outside the lung itself and must have involved the dorsal sympathetic chain and dorsal roots of the eighth cervical nerve or the brachial plexus itself to account for pain that went down the arm. Neurofibroma might be considered. A benign tumor causing little or no bony destruction may produce a Horner's syndrome and could account for the symptoms presented here. It might be endothelioma. Pancoast thought that his original tumors were endotheliomas but changed his mind. They may appear in the pleura, may invade lung tissue and may cause symptoms like those seen in this case.

Fibrosarcoma or any variety of sarcoma might possibly explain the character and symptoms of this tumor. But this tumor appears primarily as apical and less mediastinal, where the fibrosarcomas commonly arise. I do not believe that any of these tumors explain the symptomatology. I think the first two symptoms of importance in this case are pain extending down the shoulder and arm, and hemoptysis. With the presence of hemoptysis, we must presuppose that there is some where a lesion in this patient developing within the bronchus or eroding the bronchus and causing an intraluminal lesion that produced the symptoms. We come down to the final diagnosis which is certainly not Pancoast tumor. It is my impression, from the early history of hemoptysis and pain in the chest and arm, that we are dealing with bronchiogenic carcinoma of the apex of the lung, in the upper lobe bronchus. It grew relatively slowly, and was most likely a squamous cell carcinoma, showing some necrosis in the center to account for the areas of rarefaction. There must have been involvement of the dorsal chain of the left second and third ribs and invasion of the

eighth cervical nerve or of the bronchial plexus itself.

DR DONALD S. KING: As Dr. Badger has said, the important thing was the dark red sputum every day for eight months, which rarely occurs, except with bronchiogenic carcinoma.

DR EDWARD D. CHURCHILL: One of the presenting clinical manifestations in this case was the well being of the patient, who had no cachexia and no sign that is ordinarily seen with long standing illness. The point in differential diagnosis that puzzled me most was the choice between a true intrapulmonary malignant tumor and one arising outside the lung. We might have gained some more information by an artificial pneumothorax, but since the question of operability required an absolute answer, we went ahead with exploratory thoracotomy, with the provisional diagnosis of primary bronchiogenic carcinoma invading the chest wall. The pain in the arm was interpreted a bit differently from the way in which Dr. Badger analyzed it, possibly because we could determine that it was sharply localized to the distribution of the axillary branch of the second intercostal nerve. The statement that the pain was below the elbow was, I believe, incorrect. Cancer, with unmistakable evidence of nerve involvement, is usually out of bounds surgically. This proved to be so when the tumor was disclosed at operation. The growth invaded the chest wall and was clearly of intrapulmonary origin. A frozen section biopsy confirmed the diagnosis of carcinoma.

The problem was one of palliation rather than cure. We know from having seen a great many of these patients with apical carcinoma that the pain in the terminal stages is one of the worst experiences that a person must endure. There has been no way of relieving this pain by section or injection of nerve roots, and the only thing possible is high chordotomy, with its attendant hazards not only to life but loss of sphincter control and other disagreeable sequelae. In spite of the fact that the tumor had invaded the chest wall and despite the fact that there was an involved lymph node 2 cm in diameter in the anterior mediastinum, the lung in this case was removed with the hope that we should then be able to give effective deep x-ray therapy to the chest wall. X-ray therapy with the huge tumor in situ might well have produced necrosis, sequestration and secondary infection of the necrotic tumor mass. The hilum of the lung was free and contained grossly no involved lymph nodes so that the left lung was removed.

There was no evidence of a destructive process in the ribs in any of the films, and no visible calcification within the mass.

Each day, the sputum was dark reddish brown, and the patient said it had been exactly similar for the past eight months. The pain in his arm grew worse, and was no longer controlled by aspirin and codeine. On the ninth hospital day, constriction of the left pupil was noticed for the first time. The next day, an operation was performed.

#### DIFFERENTIAL DIAGNOSIS

DR. THEODORE L. BADGER:\* May we see the x-ray films?

DR. AUBREY O. HAMPTON: This first examination was made in 1938, when the chest was considered normal. There might be the slightest variation in density between the lung apices, the left being thought by some observers to be a little more radiant than the right. This next film, which was taken two years and two months later, shows a fairly homogeneous dense shadow occupying the region of the left upper lobe, with perhaps a little mottling. There is no displacement of the trachea and no disease in the ribs. The remainder of the lung fields is clear. Still later films show little or no increase in the total size of the mass, but the mottling has become more prominent and there is a strong suggestion of cavitation. These are laminographic films, and this is the same area seen on the plain film. The inferior margin of the shadow is sharp, and within it there are mottled 1-cm. to 2-cm. areas of rarefaction, which are almost like a cluster of grapes, very regular in size. Another significant finding is an unusually straight bronchus, which looks as though it were being pulled on and runs into the area of disease. It filled irregularly with lipiodol. No lipiodol entered the area of disease, and the trachea and main bronchus were not pressed on. In summary, the film shows a fairly sharply defined shadow continuous with the ribs and the apex of the lung and, in the lower portion, multiple cavities of almost the same size. There is also a straight rather drawn-out looking irregular bronchus.

DR. BADGER: Summarizing briefly this complicated and rather difficult case, the outstanding features of the history are two years of fatigue, and hemoptysis eight months before entry. At that time, a diagnosis of tuberculosis was made, followed by hospitalization, and a careful study, which, so far as I can tell, very definitely ruled out tuberculosis. I have no idea what the final diagnoses on discharge from the sanatorium were,

\*Instructor in medicine, Harvard Medical School; chief of Thoracic Clinics, Boston City Hospital.

except that fungous infection was considered. The patient returned to work four months later and remained there for two months, after which he was forced to retire. Eight weeks before admission, he developed a dull aching pain in the left chest; night sweats also appeared. The pain was in the axilla and radiated down to the forearm. The patient had fever and lost 10 pounds in weight.

Examination was negative except for local findings in the upper third of the left chest, with dullness and diminished breath sounds. No rales could be heard.

The blood and laboratory findings were entirely negative. X-ray study showed the findings that have been pointed out. The patient had, in addition, a final appearance of Horner's syndrome. It was not a complete Horner's syndrome, at least according to physical examination, since only the smallness of the pupil on the left side was noted. Nothing is said of lidlag or of enophthalmos, both of which are customarily seen with Horner's syndrome.

Our problem is to decide whether this is infection or tumor, and if it is tumor, whether it is a growth within the lung itself. The recurrence of symptoms eight months before entry, with dull pain in the shoulder, is not characteristic of tuberculosis or of any infection. I am inclined to rule out infection, which if present does not seem to be an important part of the picture, and believe that we are dealing with a tumor mass within the chest.

The pain in the upper left chest, the radiation of pain down the arm and the development of a Horner's syndrome immediately make us wonder whether we are dealing with a Pancoast tumor. Pancoast,<sup>†</sup> in his original description in 1924, reported 4 cases, in 2 of which autopsies were performed. Both were first thought to be epitheliomas but were finally diagnosed as squamous-cell carcinomas. Pancoast defines this particular tumor clinically. It must be an extrapulmonary tumor and must show no evidence of origin from the lung or bronchus. It must present erosion of the bone, in addition to pain in the shoulder and axilla that radiates down the arm, with wasting of the muscles of the hands. In all Pancoast tumors, small shadows in the far apex of the lung are visible by x-ray examination.

We must distinguish between the Pancoast tumor and the Pancoast syndrome, which we know today is caused by tumors other than those he originally described. Pancoast's final analysis was that the tumors that arose outside the

<sup>†</sup>Pancoast, H. K.: Importance of careful roentgen-ray investigation of apical chest tumors. *J. A. M. A.* 83:1407-1411, 1924.

which her temperature was normal and her light constant. She vomited several times, but vomitus was never blood stained.

Abdominal exploration was carried out on the th day.

#### DIFFERENTIAL DIAGNOSIS

DR. MARGARET GLENOY: This baby was brought the hospital because of blood-stained vomitus. cording to the history the vomiting of blood urred only on two days—the third and fourth ys of life. The most frequent cause of vomiting the newborn infant is hemorrhagic disease. There y have been a slight tendency toward hemor- agic disease in this case, but it was certainly t very great. The baby may have been breast t, and some of that blood may have come from icked nipples, but a large dark-red clot would ve been most unusual. The other thing that e would wonder about even in a newborn y is vomiting from esophageal varices. Several ol examinations were made between the fourth d tenth days of life, and none showed any blood. ey may not have been examined at the begin- ag of the hospital stay. Obviously, there was no strointestinal obstruction, and the stool forma- n was fairly normal, because it is not com- ented on after the passing of the meconium.

The outstanding abnormal finding in this rec- d is the mass in the left flank. Apparently, it d not extend beyond the mid-line. There was a lge in the flank, but no comment of any bulg- g posteriorly in the loin. Taking the meaning the words literally, I am inclined to think first all of an enlarged spleen. With an enlarged leen, the first thing that comes to mind is eryth- blastosis fetalis. This baby's blood smear owed only one nucleated red blood cell per 100 . Also, there is no comment that the vernix was lden yellow, and no mention of a large heart; scarred placenta is not mentioned. Nothing is own about the nationality of the parents, so far

the late type of erythroblastic anemia is con- rned. The spleen might have been enlarged :cause of sepsis, but there was no fever and no ukokytosis, and the differential count of the fifth x sixth day is not abnormal. The spleen might ve been enlarged because of congenital syphilis. owever, x-ray examination of the long bones was egative. No mention is made of the mother's lood Hinton reaction. Nothing is said about arasites in the blood smear. The baby might ve had congenital malaria. I do not believe that e did, however. She had no temperature rise in n days, but the absence of temperature rise does

not preclude the possibility of infection or even sepsis in a newborn infant.

I am not certain about the urinary-tract exam- ination. The pyelogram showed no excretion from the left kidney. On the basis of one pyelo- gram, I am not convinced that the tumor was renal in origin. There may have been only one kidney, but it may be that in the x-ray film the density of the mass in the left flank made the slight amount of concentration of the dye in the pelvis invisible. If this were a kidney tumor of a non- functioning kidney, one would expect to find a rather round mass, and one would also expect to find some mass in the loin. Polycystic kidneys are usually bilateral. Solitary cysts of the kidney are, statistically speaking, more frequent on the right than on the left. The Wilms tumor is the most usual kidney tumor in childhood. Sarcoma of the kidney might have invaded the vena cava in utero, producing obstruction and hence collateral circulation and bleeding from varices. Another thing against kidney tumor is the statement that the tumor was freely movable.

Abdominal exploration was carried out. One would not operate on a baby with a large spleen just because it extended from the brim of the pelvis to the thoracic cage. One would operate because there was something there that might inter- fere with the existence of that child. I have not seen the x-ray films, but my conclusion is that this baby had neoplasm of the spleen. I do not know what the type of growth was.

DR. TRACY B. MALLORY: Should you care to see the x-ray films?

DR. GLENOY: I should like to very much.

DR. JAMES R. LINGLEY: The x-ray films are quite helpful in this case, I think. They show quite definitely that this was a tumor of the kidney and not of the spleen, because on the plain film one can see a perfectly normal spleen above the mass that occupies the whole flank. This mass is very large, extending from under the costal border to the crest of the ilium and well over to the mid-line. The pyelogram shows a normal kidney on the right, with good excre- tion of the dye and absolutely no excretion on the left side. So that I consider the x-ray evidence definitely in favor of a tumor of the kidney. The lungs show nothing definite.

DR. MALLORY: Do you want to accept the x-ray evidence, Dr. Glendy?

DR. GLENOY: Certainly; I am very grateful for it.

DR. MALLORY: It is not always wise.

DR. GLENOY: May I ask why they operated?

Was the baby not doing well from any other point of view?

DR. SIDNEY FARBER:\* No; they operated for one good reason: the nature of the large firm mass in the left flank could not be determined without surgical intervention.

DR. FLETCHER H. COLBY: In babies with enlarged spleens, do you ever find that the enlargement is sufficient to cause nonfunctioning of the kidneys? Does it always cause displacement, but not nonfunctioning?

DR. FARBER: Disturbance of kidney function caused by an enlarged spleen must be extremely rare.

#### CLINICAL DIAGNOSIS

Hemorrhage into left adrenal gland.

#### DR. GLENDY'S DIAGNOSIS

Congenital tumor in left flank, probably arising from spleen.

#### ANATOMICAL DIAGNOSIS

Neuroblastoma sympatheticum of left adrenal gland.

#### PATHOLOGICAL DISCUSSION

DR. FARBER: Many years ago, I learned by sad experience that it was unwise to take too seriously clinical palpation of the notch of the spleen as evidence that a mass in the abdomen represented the spleen. The report in the history of the palpation of a notch was definitely misleading. The patient under discussion today was seen in 1933. For that reason, no information such as might be obtained today concerning the nature of the hemorrhagic episode observed soon after birth is available. I believe that Dr. Glendy's choice of hemorrhagic disease with spontaneous improvement is probably the correct explanation for the vomiting of blood. The surgeon, Dr. George Cutler, resorted to operation because the nature of the large mass that was palpated could not be determined by any clinical or roentgenologic method of study with any degree of accuracy. The clinical diagnosis was massive adrenal hemorrhage. The presence of a malignant tumor was suspected. At operation, Dr. Cutler removed a mass that lay immediately above the left kidney replacing the adrenal gland. It was completely encapsulated and could be stripped without difficulty from the surrounding structures. It

weighed over 100 gm. and was round and smooth, and the capsule was intact. The cut surface disclosed a mass divided into a number of lobules containing hemorrhagic necrotic tissue. The final pathological diagnosis was neuroblastoma sympatheticum, which had undergone extensive hemorrhagic necrosis.

The subsequent story may be of some interest. The infant recovered soon after the operation; eight years after that procedure, the child is still alive and in good health. Certainly, the patient has passed far beyond the point where metastasis or recurrence might be expected. I might add that no radiation or any other treatment directed at the tumor was employed at any time.

I should like to make some remarks concerning one of the questions that arose in the matter of differential diagnosis. The pyelogram is of no real aid in the accurate diagnosis of tumors of the kidney region in early life, and may indeed mislead the surgeon if too much reliance is placed on interpretation of the x-ray films. In the first place, it is impossible to tell by means of the pyelogram whether the tumor is within the kidney or within the adrenal gland, or whether the tumor is unattached in the region of the kidney. A neuroblastoma arising from the adrenal medulla may cause just as much obstruction to the ureter as an embryoma arising within the kidney. Furthermore in 3 cases, I have seen a neuroblastoma arise from an adrenal gland in which the growth rested within the substance of the kidney and was responsible for an x-ray picture and a gross pathologic specimen that could not be differentiated from an embryoma of the kidney. In the second place, it is of little importance to know before operation whether the mass is within the kidney or in the immediate vicinity of the kidney. The exact location of the tumor must be determined by the surgeon at the time of operation. The only real use for a pyelogram in infants or children suspected of having a tumor in the kidney region is to provide an easy method of demonstrating that two kidneys are present, in the event that the surgeon must remove one kidney with the tumor.

A second point worthy of special emphasis concerns the reason for operation and exploration of the abdomen of this young infant in whom the main finding was a mass in the abdomen. For many years, we have been guided by Dr. S. Burt Wolbach's generalization concerning tumors of early life, which has been well borne out by repeated tests. This is: *every solid mass in early life is to be regarded as a malignant tumor until*

\*Assistant professor of pathology, Harvard Medical School; pathologist, Children's Hospital.

*proved otherwise by pathological examination* Although blanket rules are at times quite dangerous, this generalization has settled many a discussion concerning the proper method of treatment in problems of this kind and has not led us into erroneous or harmful decisions

By neuroblastoma sympatheticum I mean the malignant variety of the series of tumors arising in the sympathetic nervous system The true nature of this tumor, incidentally, was demonstrated at the Massachusetts General Hospital by Dr Jomer Wright in 1911 In a series of 40 neuroblastomas, which occurred in a ten year period at the Boston Children's Hospital, more than half arose in situations outside the adrenal medulla About one fourth of these 40 patients are alive and apparently well after operative removal of the tumor and histologic verification of its nature The tumor is extraordinarily radiosensitive In 2 cases, cures have been obtained by means of radiation therapy after metastases to the liver had been proved

by histologic study My experience in recent years has led me to conclude that the opinion in the literature concerning the almost universally bad results with the neuroblastoma is not a correct one At the present time, the method of choice in the treatment of the neuroblastoma is removal of the primary tumor, with subsequent radiation of the area involved by the tumor Radiation therapy should also be applied to areas involved by metastatic tumor

A PHYSICIAN. How often are tumors of the adrenal gland as readily movable as the one described in this case?

DR. FARBER. Not often. If the tumor is readily movable, it is more apt to be one arising in the periadrenal tissues rather than in the adrenal gland or in the kidney tissue.

A PHYSICIAN. Was the kidney involved?

DR. FARBER. No; it was just pushed aside by the tumor mass

## COMBINED SEROTHERAPY AND CHEMOTHERAPY IN PNEUMONIA

SINCE the introduction of effective sulfonamide drugs, the question of whether specific antipneumococcus serums have any further place in the treatment of pneumonia has been the subject of great controversy. Most physicians may no longer consider this problem of any importance, since they are only occasionally called on to treat patients who are severely ill with pneumonia, and since they have already had an opportunity to convince themselves of the effectiveness of sulfapyridine and sulfathiazole in their cases.

Physicians who treat large numbers of cases, however, are still confronted with some patients

whose response to drug treatment is not entirely satisfactory. There are two schools of thought with respect to the additional use of serum in these cases. In one group are those who, like Janeway and Beeson,<sup>1</sup> believe that the additional use of serum in such cases increases the chances for recovery and shortens the duration of acute illness. They recommend the combined use of chemotherapy and serotherapy as the most satisfactory form of treatment in severe pneumonia. In the other group are a large number with a growing conviction that serums have little or nothing to offer in cases in which sulfonamides alone fail. Each of these views has had strong support from controlled clinical studies, which have been recently published. Two reports in particular may be mentioned.

Dowling, Abernethy and Hartman<sup>2</sup> studied a series of patients with Type 1 through Type 8 pneumonias who were alternated for treatment with sulfapyridine alone and with sulfapyridine in addition to specific antipneumococcus serum. Treatment was begun in each therapeutic group as soon as the type was determined. The mortality rate was 12.5 per cent in the group receiving sulfapyridine alone, and 9.8 per cent in the group receiving serum and sulfapyridine. When the Type 3 cases were omitted, the mortality was 9.2 per cent in patients treated with the drug alone and 4.5 per cent in those who received serum in addition. Serum was found to be particularly valuable as an adjunct to sulfapyridine in patients over forty years of age. Crisis occurred more frequently and was prompter in the patients receiving serum in addition to sulfapyridine. These authors suggested that the combined use of serum and chemotherapy be given to patients with pneumonia who are over forty years of age and also to those who are in need of a prompt defervescence.

Those who are not enthusiastic about the use of serum and who consider that its cost and the additional expenditure of the time and effort required in its use are not justified by the additional benefits to the patient may take solace in a re-

port by Plummer and his associates<sup>3</sup> at Bellevue Hospital. These authors used a number of sulfonamides and alternated all patients for treatment by type between chemotherapy with one of these drugs alone and combined chemotherapy and serotherapy. In this study, the results were the same in both groups, regardless of whether the patient was treated early in the disease, whether bacteremia was present, whether the patient was old, and whether systemic disease was present. The authors are, however, willing to concede, "There will probably be no disagreement with the statement that serum should be used for patients who cannot tolerate the sulfonamide drugs or for those who fail to respond satisfactorily within twenty-four to forty-eight hours to drug therapy." They also mention that in their private practice they have used serum several times with gratifying results for patients who failed to respond to chemotherapy, although obviously they cannot say whether these patients would not eventually have recovered without the use of serum.

Finland, in this issue of the *Journal*, points out some of the difficulties involved in carrying out carefully controlled clinical studies on the use of serums. A number of the pitfalls in the Bellevue study are mentioned, and many more can be found on careful perusal of the data presented. Certain important information is also lacking. In particular, the alternation of cases by type could not have been so strict as the authors claim and yet have the series end with 6 more Type 2 patients and 4 more Type 13 cases in one or the other of the two groups. Furthermore, drug treatment was started in all cases immediately, and alternate patients were placed in the serum-plus-drug groups after the type was determined, regardless of whether it was unnecessary to administer serum, because the patient was dead or well. It is stated that the interval between the start of the drug treatment and the time serum treatment was begun was "usually within the first twenty-four hours." Since it is known, however, that the vast majority of patients with pneumonia who eventually respond to chemotherapy already

give clear evidence of a favorable response within this period, it is obvious that those who actually received serum were, in most cases, the patients who had responded poorly to chemotherapy.

Although the conclusions drawn by the Bellevue workers from these cases may or may not prove to be correct, Finland points out that the results of studies of this sort are "not only inconclusive but even grossly misleading," since they make unwarranted claims of scientific control. The results here, as in many other studies, are influenced by important factors in the choice of cases that are either unrecognized or merely ignored. Obviously, the "choice" is usually exercised unconsciously.

Combined serotherapy and chemotherapy will certainly not be used routinely by the vast majority of physicians. It is only in the severe cases and in those patients who are unable to tolerate the sulfonamides that the early use of serum in addition to the drug is justified. The usefulness of serum when the drugs fail is generally conceded.

#### DIRECTORY OF MEDICAL SPECIALISTS

THE second edition of the *Directory of Medical Specialists*, which will be ready for distribution in February, 1942, will list the names of approximately 18,000 diplomates of the fifteen American boards that examine candidates for certification in the specialties; this is 4000 more than were included in the first edition, which was published early in 1940.

The geographic grouping will give completely revised biographic data about each diplomate, including much information not found in the first edition, such as military appointments and the details of formal training. In addition, the plan of organization, the officers and the examination

requirements of each American board will be fully outlined.

The *Directory* again presents a list of physicians and surgeons who have had excellent training and adequate experience in their chosen fields and who have limited their practice to those fields. This official record of specialists is invaluable as a reference: it provides essential data concerning qualified specialists throughout the United States and Canada, information that is extremely useful to the officers of medical societies and to physicians who refer patients to associates in distant communities.

The new edition will probably be as much in demand as its predecessor, which had a wide distribution, not only among the members of the medical profession and medical libraries, but also among insurance companies and firms that manufacture and distribute medical supplies.

## MEDICAL EPONYM

### KERNIG'S SIGN\*

Vladimir Michailovich Kernig (1840-), ordinator at the Obuchow Hospital in St. Petersburg, reported "Ueber ein wenig bemerktes Meningitis-Symptom [A Little-Noticed Symptom of Meningitis]" in the *Berliner klinische Wochenschrift* (21: 829-832, 1884). A portion of the translation follows:

For a number of years, I have noticed in the cases of meningitis that have come under my attention a symptom that seems to be little known, although in my opinion it has a definite, practical value. I refer to the occurrence of a flexion contracture in the legs, occasionally occurring also in the arms, which is first seen when the patient sits up. . . . If the patient sits on the edge of the bed so that the legs hang over (in cases with very marked stiffness of the neck and back this is not easily accomplished), the contracture of the neck and back usually becomes much more marked. Furthermore, there is now observed a flexion contracture in the knee joint and occasionally, also, in the elbow joint. Extension of the patient's leg at the knee is now only possible to an angle of about 135°, or if the phenomenon is marked, only to a right angle. . . . I am also convinced that, with the patient in the dorsal position, this contracture appears when the extended leg is brought to a right angle with the trunk. In normal patients, no similar contracture is seen with the same degree of flexion of the hip.

### SECTION OF OBSTETRICS AND GYNECOLOGY\*

#### FATAL DIABETIC COMA IN PREGNANCY

A thirty-year-old para II was first seen when she was approximately thirty-two weeks pregnant. She had had diabetes for ten years and had been followed by a hospital clinic. She had always been most unco-operative and had been in the hospital in diabetic coma twelve times prior to the present admission. The previous pregnancy terminated in a premature breech delivery at six months. The baby was stillborn, and the patient herself was in diabetic coma.

The patient was kept in the hospital about three weeks. At the end of this time, since she was somewhat over thirty-six weeks pregnant, it was decided to deliver her by cesarean section and sterilize her. She was presumably in good condition from the standpoint of the diabetes on the morning of operation. After the administration of 3 gr. of Nembutal and 15 cc. of paraldehyde in oil, she was taken to the operating room. Her condition suddenly became extremely serious, and the blood pressure dropped to 82 systolic, 50 diastolic, and the pulse rose to 172. The operation was postponed, and on the same afternoon the blood pressure rose very suddenly to 202 systolic, 90 diastolic. The patient developed a right-sided facial paralysis and died undelivered.

*Comment.* Pregnancy in diabetes is much more frequently seen than it was in the preinsulin days, and a death such as this should be extremely unusual. Well-organized diabetic clinics have no fear for the mother's life. Not yet can a living baby be guaranteed in every diabetic pregnancy. It is true that this patient was most unco-operative, but in the light of the experience of other diabetic clinics it does seem that this maternal death could be attributed solely to unskilled handling of the diabetic problem. The average practitioner has learned that insulin almost always controls diabetes very easily. The average diabetic specialist who has not seen much of the complication of pregnancy does not appreciate the instability that pregnancy places on these patients. This can fairly be called a preventable death. If deaths occurring in diabetic patients during pregnancy are to be prevented, the pregnancies of these patients must be handled by trained diabetic specialists and those who have had particular experience in handling the problem.

\*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters should be addressed to Dr. Raymond S. Titus, Secretary, 330 Dartmouth Street, Boston.

## DEATH

September 11, 1941

FULLER—ERNEST P FULLER, M.D., of Lawrence, died September 14. He was in his sixty ninth year.

Born in North Andover, he graduated from New York University College of Medicine in 1899. Dr Fuller was on the staff of the Lawrence General Hospital, and was a fellow of the Massachusetts Medical Society and the American Medical Association. He held memberships in the Lawrence and North Essex medical clubs.

His widow, a daughter, three grandsons, three sisters and a brother survive him.

## NEW HAMPSHIRE MEDICAL SOCIETY

## DEATHS

ABBOTT—CHARLES B ABBOTT, M.D., of Hillsboro, died March 24. He was in his seventeenth year.

Dr Abbott, the son of Benjamin and Mary (Choate) Abbott was born in Bradford and graduated from Dartmouth Medical School in 1902. He was a member of the New Hampshire Medical Society.

He is survived by his widow and a sister.

WEINBERG—PHILIP B WEINBERG, M.D., of Whitefield, died August 27. He was in his fifty fourth year.

Born in Berlin, Germany, Dr Weinberg received his degree from Tufts College Medical School in 1920. He was a member of the New Hampshire Medical Society and the American Medical Association.

He is survived by his widow, three brothers and three sisters.

## CORRESPONDENCE

## COMBINED SEROTHERAPY AND CHEMOTHERAPY IN PNEUMONIA

To the Editor: In the paper entitled, 'Controlling Clinical Therapeutic Experiments with Specific Serums,' which appears in this issue of the *Journal*, is included a criticism of a study that was published from Bellevue Hospital. In view of this, I took the liberty of sending a copy of the manuscript to Dr Norman Plummer, prior to publication, and have received the following reply: 'I believe it is only fair that you publish this letter, and you have Dr Plummer's permission to do so.'

I believe that the arguments brought forth by Dr Plummer serve only to emphasize the whole theme of my discussion, namely, that it is impossible to carry out large scale clinical experiments with strictly scientific controls that are not open to criticism. As a single example, if one works out the probability that the difference in the twenty four hour deaths in the two groups is a matter of chance, one finds that it is approximately one out of thirty five times.

It is only because we have ourselves been so thoroughly disillusioned when reviewing the results of our clinical results, which we thought were carefully controlled, that we became convinced of how difficult it is to carry out such experiments.

MAXWELL FINLAND

Boston City Hospital  
Boston

Dear Dr Finland: Your paper arrived a few days ago, and I appreciate your consideration in sending it to me. Perhaps I can clarify some of the points to which you refer in your criticism.

You state, 'Some of the patients were already dead and others were afebrile at the time the type was determined, they received no serum, but were nevertheless retained in the group receiving combined treatment.' The statement implies that this was not the way in which to handle the alternation of cases. The plan we had in mind from the start was to handle the series as though the patients were being treated in two different hospitals. On the shelves of the one hospital there was a supply of sulfonamide drugs, and on the shelves of the other there were both sulfonamide and serum. Everything else was the same for the two groups of cases. In each series the effort was made to obtain the best results possible under the circumstances of the experiment. We realized that one disadvantage of specific serum was the delay in administration caused by the time required for typing. It is true that a few (6) patients dying within twenty four hours were dead before the typing was obtained. Should these cases have been removed from the series? To do so would not be legitimate unless the cases in the chemotherapy alone series were treated in the same way, and any attempt at such manipulation would certainly be open to criticism. Some patients (actually 95 of the 301 cases) were so fully recovered that, when the typing was obtained serum was no longer indicated. The serum was available had there been any use for it. What should be done with these cases? To remove them, and to offset this by removing similar cases from the other group, again would be difficult and would be a manipulation of the experiment.

You state, 'It is rather odd, in view of the strict alternation in type stressed by these authors, that for many of the types there is a preponderance of cases either in the series treated with the drug alone, or in the combined therapy series.' By this, you refer to there being in Type 2, 49 cases on the one side and 55 on the other, in Type 5, 24 and 27, in Type 13, 5 and 1, in Type 18, 3 and 6, in Type 19, 8 and 5, and in Type 20, 7 and 4. This discrepancy can be quickly explained while we used strict criteria for making the clinical diagnosis, there were cases included and alternated that, on later analysis, were proved not to have pneumonia. This was particularly striking in Type 2, because during one season there was a high incidence of Type 2 pneumococci in severe upper respiratory infections. Furthermore, our experiment was opened and closed three different years, which again created some of this discrepancy.

Again you state, 'The length of the delay before serum treatment was given in most cases is not mentioned.' The typing was done in a pneumonia laboratory by experienced technicians giving a twenty four hour service. Emphasis was placed on rapidity and accuracy. The delay in obtaining types was probably equal to that which you encounter on your service and much less than that in the average large hospital. Because of the quality of typing service which we maintained, the results obtained in our combined group should have been better than would have been expected were the typing less efficient.

You continue with this statement, 'Furthermore, although mention is made of the number of patients who received serum and died within twenty four hours, the total number of patients who actually received serum

is not given." You failed to get the important point of our study: namely, that we were not comparing the results with serum and no serum, but the results in a series of having the benefits of both drug and serum with those in a series having only the drug. Actually 62.4 per cent of the patients in the serum series received serum, and only 6 of the cases due for serum died before it could be given.

Your next statement is, "Moreover, a considerable portion of the mortality among the patients who received combined treatments occurred within twenty-four hours of admission to the hospital, whereas only a small number of those receiving drug alone died within twenty-four hours of entry." This was exactly the way the series turned out, and it shows how the laws of chance operate in such a study. The fallacy of including the twenty-four-hour deaths is well recognized, and that is the reason why we show these cases apart from the rest of the series.

You further state: "... it seems much more probable that some unconscious selection on the part of the authors played an important role in the inclusion of the poorest subjects among the serum recipients. This is only a natural occurrence, since there is always a tendency to give to the patients who seem the most severely ill the benefits of any remedy that is known to be effective." We avoided such a possibility by taking a number of precautions. There were a number of physicians treating the patients, and they had nothing to do with the alternation of the cases. This was done in the laboratory by the technicians, who again had no knowledge whatever of the clinical condition of the patients. Furthermore, the serum was kept in the laboratory and delivered to the ward when a serum case was discovered. On this basis, how there could have been a conscious or unconscious selection, I am at a loss to explain. With such criticism as you did offer you must consider the possibility of manipulation at the time the list was compiled. Actually, the list was compiled by seven different persons, and at the time the columns were added no one had the slightest conception of how the series turned out.

Finally, you conclude, "The conclusions drawn by these authors may or may not prove to be correct, but one cannot help believing that the results as presented are not only inconclusive but are even grossly misleading." If you will reread the paper, you will note that we avoid sweeping conclusions.

I was amused at your final paragraph, in which you say, "It is my opinion that this particular question as it concerns pneumonia is now a highly academic one, since it is unlikely that any physician would contemplate using the combined therapy as a routine in all cases." Originally, we concluded our paper with: "Our results indicate that serum no longer plays a role in the routine treatment of pneumonia," but we thought that this statement was too strong. In presenting our study, we had no desire to draw conclusions, but we did make every effort to tabulate our results as accurately as possible. The omission of the figures mentioned by you was not done to mislead anyone, but to make the article as concise and brief as possible. There was not a single individual in our group who had a preconceived opinion regarding the outcome of the investigation. All of us had used serum enthusiastically and had no reason to oppose its use. Furthermore, our active group received constant counsel from the directors of our divisions, Dr. Cecil and Dr. Sutliff, and it hardly seems possible that they would allow us to be so "grossly misleading."

I have tried to answer your criticism as completely as possible, but if there is any point which is not entirely covered, I shall be pleased to discuss it further with you.

Yours sincerely,

NORMAN PLUMMER

The New York Hospital  
New York City

## NOTICES

### ANNOUNCEMENTS

DR. HILBERT F. DAY announces the removal of his office from 412 Beacon Street, Boston, to 34 Kirkland Street, Cambridge.

DR. LEO J. McDERMOTT announces the removal of his office from 372 Longwood Avenue, Boston, to 151 Vaughan Street, Portland, Maine.

DR. AUGUSTUS RILEY announces the removal of his office from 868 Beacon Street to 59 Bay State Road, Boston.

### JOHN T. BOTTOMLEY SOCIETY

The regular monthly meeting of the John T. Bottomley Society will be held in the Out-Patient Building of the Carney Hospital on Wednesday, October 1, at 11:30 a.m.

Physicians and students are cordially invited to attend.

### BOSTON DOCTORS' SYMPHONY ORCHESTRA

The Boston Doctors' Symphony Orchestra will resume rehearsals, under Alexander Thiede, on Thursday, October 9, at 8:30 p.m. at Station WMEX, 70 Brookline Avenue, Boston. Those interested in becoming members should communicate with Dr. Julius Loman, 520 Beacon Street, Boston (KEN 3200 or LON 2155).

## CARCINOMA OF THE LUNG: BRONCHOSCOPIC ASPECTS\*

RENE H. BETTS, M.D.†

BROOKLINE, MASSACHUSETTS

**B**RONCHOSCOPY is the most important method of diagnosis in primary carcinoma of the lung. Such new growths appear to be on the increase and now cause from 8 to 18 per cent of all deaths due to cancer, as reported by Jaffe,<sup>1</sup> Kolesky,<sup>2</sup> Simons,<sup>3</sup> Graham,<sup>4</sup> and Ochsner and DeBakey.<sup>5</sup> Approximately 75 per cent of such tumors arise in the major bronchi, as shown by Tuttle and Womack,<sup>6</sup> Gebauer,<sup>7</sup> Broyles and Fisher,<sup>8</sup> and Overholt and Rumel.<sup>9</sup> Lesions so situated can be visualized and biopsied bronchoscopically.

In 1933, before the advent of pneumonectomy for cancer of the lung, bronchoscopic investigation of such cases was infrequent. The high percentage of positive diagnoses that would be obtained by his method of investigation if all persons suspected of having pulmonary neoplasms were studied endoscopically is still not generally appreciated. In 1939, Taylor<sup>10</sup> stated that "confirmation of lung tumors is not usually available preoperatively. . . ." This statement may have been true, but need not be true today if all patients with unexplained pulmonary symptoms are studied bronchoscopically.

The patient with a change in bowel function rightfully deserves a proctoscopic examination. Abnormal urinary symptoms often indicate the desirability of cystoscopic studies. Likewise, the patient with unexplained pulmonary symptoms cannot be considered fully investigated without a bronchoscopic inspection of the trachea and bronchial tree.

Establishing a verified diagnosis of cancer at an early stage of the pathologic process should not be so difficult in neoplastic lesions of the lung as in other internal organs. In a personal series of 62 cases with histologically verified primary neoplasms of the lung, the lesion was seen and a positive preoperative diagnosis of cancer made from the biopsy specimen in 46 cases (74 per cent). In con-

trast with this, cancers of the kidney, gall bladder, pancreas, stomach, brain or colon, with the exception of the rectum and sigmoid, are practically never histologically verified before exploration. The high percentage of preoperative positive biopsies in cases with a pulmonary neoplasm should make this lesion one of the most favorable types. This report is presented to demonstrate the value of bronchoscopy in the diagnosis of pulmonary tumors and its application to the determination of operability and expedition of therapy.

### PRESENT-DAY BRONCHOSCOPIC EXAMINATION

Endoscopic investigation of the tracheobronchial tree should not be delayed because of hesitancy on the part of the physician or fear on the part of the patient. It is not an ordeal to be endured, but rather it is an examination that can be performed easily under local anesthesia, with minimal discomfort and with little inconvenience to the patient. Therapeutic bronchoscopies may be satisfactorily managed in an outpatient department, but diagnostic investigations are preferably done as a hospital procedure. The patient is admitted the day before and is ready for discharge the day following the examination. Such a routine permits adequate investigation and preoperative medication, the latter being a valuable adjunct to local anesthesia. Patients are taken to the operating room conscious, but relieved of the sense of anxiety and fear by a barbiturate two hours previously, and by morphine and scopolamine subcutaneously one hour preoperatively. Topical application of cocaine or Larocaine to the hypopharynx and each pyriform sinus is supplemented by the intratracheal instillation of a few cubic centimeters of a diluted solution of the same agent. Painful impulses from the upper respiratory tract are thus abolished, the irritative sensation of a foreign body in the tracheobronchial tree is alleviated, and the cough reflex is suppressed.

Proper teamwork is essential for this type of

\*From the New England Deaconess Hospital.

†Consulting thoracic surgeon, New England Deaconess Hospital.

endoscopic work. Inadequate preparation, inexperience and lack of teamwork on the part of the operator and assistants are responsible for the common misconception that bronchoscopic examination is a severe ordeal for the patient. With the patient in the dorsorecumbent position, with the head and shoulders projecting over the end of the table, the head is held forward and extended on the cervical vertebrae. In this position, a straight line is formed from the open mouth to the trachea. A straight, nonflexible tube, such as the bronchoscope, can then be inserted into the trachea without trauma.

A careful and complete examination of the trachea and the visible portion of the bronchi can be carried out in a few minutes. A definite routine of inspection, including examination of all major bronchi, should be followed to obtain all the information possible. Patients frequently express surprise at the lack of discomfort, and in many cases they do not even remember the procedure the following day, especially if scopolamine has been administered preoperatively. When the investigation is performed carefully, it is practically without risk.

INDICATIONS FOR BRONCHOSCOPY

Bronchoscopic examination is indicated in every patient who is suspected of having a primary pulmonary cancer, except for the patient with obvious widespread metastases. Practically all patients with neoplastic lesions have some respiratory symptom. Ninety-eight per cent of the series reported by Overholt and Rumel<sup>9</sup> had definite symptoms that indicated an abnormality of the respiratory system. They found cough to be the most frequent symptom (87 per cent); fever was next (53 per cent); and chest pain or discomfort was third (44 per cent). Hemoptysis, marked weight loss and symptoms due to metastatic lesions are usually late signs and should not be awaited before institution of adequate investigation. The disease is most frequently encountered in the fourth and fifth decades, but the extremes are not uncommon. The age of the patients in the present series varied from eighteen to sixty-seven years.

It is not the intention of this report to promote the idea that all patients with pulmonary symptoms should have a bronchoscopic examination. However, all patients with unexplained pulmonary symptoms do warrant this investigation. Cases of pneumonia that are atypical and do not respond to the usual therapy in a few weeks may be due to bronchial obstruction by a tumor. Recurrent pneumonia of the same lobe may be due

to intermittent atelectasis of that lobe. Development of a respiratory wheeze, especially in a patient without past allergic history or in one who does not respond promptly to allergic therapy, necessarily places that patient in the class in which cancer is suspected.

The etiologic factor in most pulmonary lesions becomes apparent after a careful history has been taken, after a complete physical examination has been made, and after adequate roentgenologic studies have been secured. Sputum, if obtainable, should always be examined for both acid-fast bacilli and other organisms.

It is the patient who is still not diagnosed after performance of the above studies who warrants bronchoscopic examination. Even a roentgenologic diagnosis of pulmonary cancer is not sufficient, since a verified diagnosis cannot be made by this method. Too often, the physician becomes discouraged and goes no farther after receiving a report of primary lung cancer from the roentgenologist. Furthermore, the extent or operability of a given lesion may be misleading by roentgenography. Bronchoscopy is the most accurate way of determining both these factors.

CLASSIFICATION

From the bronchoscopic viewpoint, pulmonary carcinomas may be conveniently divided into two groups, central and peripheral, depending on the site of origin of the lesion. The central or stem-bronchus group (Figs. 1 and 2) includes those arising in the larger air passages, that is, proximal to the bifurcation of the bronchi of the third order. In other words, these lesions arise in the main bronchus, in the lobar bronchi or in the proximal portion of one of the lobar bronchial subdivisions. Lesions in this central group comprise approximately 75 per cent of all primary neoplasms. If the tumor itself can be seen endoscopically, it necessarily falls in the central classification. Peripheral tumors include all those arising beyond the proximal segment of a bronchus of the third order. They cannot be directly visualized by bronchoscopy, although frequently a deformity of the bronchus may be noted owing to an inward displacement by pressure of the tumor mass. Such an observation is strong presumptive evidence of neoplasm, although tissue may not be obtained for histologic examination. Bronchoscopy is the most accurate way of determining whether the lesion is central or peripheral.

For three reasons, tumors falling in the central group of neoplasms seem more favorable from a therapeutic standpoint. First, a new growth in a major air passage produces symptoms earlier than

one distally situated, since it soon encroaches on the lumen of the bronchus and thus gives rise to symptoms; peripheral tumors usually have to be of considerable size before structures are involved that will cause the patient to realize there is something abnormal. Secondly, lesions arising in main or lobar bronchi can be visualized and

though there was no roentgenographic evidence of disease.

### *In Late Primary Lesions*

As soon as the growth reduces the lumen of the bronchus appreciably, abnormal physical signs and roentgenographic abnormalities appear. From

FIGURE 1. Roentgenograms of Chest.

A shows partial atelectasis of the right upper lobe. Owing to the presence of diffuse bilateral calcified foci, the patient was treated for pulmonary tuberculosis in a sanatorium for seven months, in spite of a negative sputum. B, taken six months later, shows progression of the lesion to complete atelectasis. A diagnosis of epidermoid carcinoma was established by bronchoscopic biopsy.

biopsied bronchoscopically, thus permitting an earlier verified diagnosis, with resultant improvement in treatment. Thirdly, there is evidence (Tuttle and Womack<sup>4</sup>) to show that tumors in the central location grow more slowly and metastasize later than lesions situated peripherally.

### USES OF BRONCHOSCOPY

#### *In Early Primary Lesions*

A small submucous bronchial lesion may not produce pulmonary signs or symptoms. When such a tumor extends intrabronchially or breaks through the mucosa, it produces cough or, if ulceration is present, hemoptysis. Depending on the size and configuration of the neoplasm, roentgenographic findings may or may not be present. Few cases are observed at such an early period, yet the lesion may be visible bronchoscopically. In one case in this series, investigated because of hemoptysis, a diagnosis of pulmonary carcinoma was established by bronchoscopic biopsy even

meager physical and roentgenographic findings to most striking signs may represent a very short period in the tumor cycle. When a major bronchus becomes occluded, that portion of pulmonary parenchyma supplied by it becomes atelectatic; hence, marked signs become apparent. The extent of the findings on physical and roentgenographic examinations is not a criterion of the extent of the disease, since a mass 2 or 3 cm. in diameter located in a main bronchus may produce atelectasis of the entire lung. If such a tumor were primarily intrabronchial, it might well not have extended beyond the realm of resectability. Bronchoscopic visualization of the tumor gives a much more accurate knowledge of its extent than either physical examination or roentgenography.

#### *In Metastatic Lesions*

The lungs are frequently the site of metastatic implants from distant organs. As a rule, pulmonary metastases reveal themselves as multiple, well-defined, discrete shadows in the pulmonary

parenchyma and cannot be visualized bronchoscopically. On occasion, an implant may involve the wall of a major bronchus and produce roentgenographic findings of atelectasis, which cannot be differentiated from those produced by a primary bronchiogenic neoplasm.

In two cases, I have obtained positive biopsies bronchoscopically in tumors that were not bronchiogenic in origin. One was a lymphoma with involvement of the left lower-lobe bronchus, and the second was a metastatic implant from a mel-

FIGURE 2. Roentgenogram of Chest

*In this patient, who was sixty-seven years of age, with a history of a moderately productive cough of two months' duration, a presumptive diagnosis of bronchiectasis had been made. Bronchoscopic examination revealed a primary bronchiogenic carcinoma. Note the haziness of the right lower lung field. Pneumonectomy was successfully performed.*

anotic sarcoma of the eyelid, the original tumor having been removed four years previously.

#### Other Uses

Bronchoscopy should not be limited to the one function of establishing a histologically verified diagnosis. Information of great value in determining the plan of treatment can be obtained by a complete bronchoscopic visualization of the trachea and major bronchi.

**Determination of operability.** Radium, roentgen rays and surgery are the three methods available for treating primary carcinoma of the lung. Reports have appeared in the literature by Leucutia,<sup>11</sup> Brock<sup>12</sup> and Leddy and Moersch<sup>13</sup> of five-year cures by radium or roentgen-ray therapy, or

both. Surgery, by far, gives the greatest hope for cure.<sup>4, 9, 11</sup> Hence, it is necessary to have indisputable evidence that the lesion cannot be removed surgically before denying the patient this chance for surgical cure. Metastases to bone, brain and other organs frequently take place. If such extrathoracic extension cannot be demonstrated, evidence of local extrapulmonary involvement should be searched for. One cannot always be certain bronchoscopically that a given lesion is operable. Various findings, however, may demonstrate that extrapulmonary extension has taken place, and that the lesion is therefore inoperable. Bronchoscopy may thus save the patient a thoracic exploration.

Bronchoscopic evidence of inoperability may be grouped under two headings: local intrabronchial direct extension to an unresectable area of the tracheobronchial tree, and extensive paratracheal lymph-node involvement.

Lesions originating in either the main-stem or the right upper-lobe bronchus may extend so as to invade the wall of the nearby trachea. Such

FIGURE 3.

*This drawing illustrates how a lesion originating in the vicinity of the upper-lobe orifice may, by direct extension, invade the nearby trachea and become unresectable.*

an extension can be visualized bronchoscopically and inoperability determined (Fig. 3). A not infrequent finding is involvement of the contralateral main-stem bronchus. This appears to take place by extension from the infracarinal lymph nodes (Fig. 4).

The lymphatic drainage of the lung is primarily

centripetal. When an extrapulmonary lymphatic extension takes place, the paratracheal lymph nodes are usually the first to be involved. Such involvement, if extensive, causes the angle between the two main stem bronchi to become more obtuse

FIGURE 4

*This drawing illustrates extension to the contralateral bronchus by direct extension from a paratracheal lymph node*

Fixation may be present, just as a so called frozen pelvis is found in advanced cases of carcinoma of the cervix. The extent of mediastinal fixation can be determined by palpating these structures with the tip of the bronchoscope. The finding of a widened carina with hardened and fixed structures, as determined bronchoscopically, is prima facie evidence of mediastinal metastases, especially if a positive biopsy from the primary site has been obtained (Fig 5).

**Therapeutic value of bronchoscopy.** The usefulness of bronchoscopy is not confined to diagnosis or determination of proper treatment. It may be of therapeutic value itself. Frequently, the bronchial obstruction produced by a neoplasm causes an infectious process in the segment of lung supplied by that bronchus. Gentle bronchoscopic dilatation or even removal of a portion of the tumor mass provides better drainage and may give relief from the septic process. Repeated bronchoscopic aspirations are occasionally indicated in such cases to improve the patient's general condition preoperatively. In certain cases not amenable to surgery, radium or radon may be used in an intrabronchial applicator introduced

bronchoscopically. This procedure has been recommended as a means of destroying the intrabronchial portion of the tumor to provide drainage for the outlying pulmonary parenchyma. My experience with this type of treatment is too meager to permit drawing conclusions.

#### BRONCHOSCOPIC RESULTS

Of 62 patients\* with histologically verified pulmonary tumors examined bronchoscopically, 49 were men and 13 women, a ratio of 4:1. Their ages ranged from eighteen to sixty-seven years, with an average of fifty-two years.

The tumor originated in one of the major bronchi in 46 patients, and was more peripherally located in 16. In 46 patients (74 per cent)—45 (98 per cent) with central tumors and 1 (6 per cent) with a peripheral tumor—a biopsy and subsequent histologic diagnosis of neoplasm were obtained. The patient with a central tumor in whom a biopsy was not obtained had an inoperable lesion originating in the left upper lobe bronchus (determined at autopsy). At the time of bronchoscopy, there was so much fixation of the mediastinal structures that the bronchoscope could not be introduced as far as the upper lobe orifice, therefore, tissue was not obtained by bronchoscopy in this particular case, although a clinical diagnosis of inoperable bronchiogenic carcinoma was established.

#### Location of Tumor

The frequency of involvement of each bronchus in the series of 46 central tumors was as follows: right upper, 10; right main stem, 10; right lower, 9; left lower, 7; left main stem, 5; left upper, 3; and right middle, 2.

Thirty-one, or 67 per cent, originated on the right side, and 15, or 33 per cent, on the left. Inasmuch as satisfactory closure of the bronchus is technically the most difficult part of a pulmonary resection, it is unfortunate that the region of the right upper lobe bronchus is most frequently involved. This bronchus arises from the right main stem bronchus, from 15 to 20 cm from the trachea. A growth originating in this area may early invade the wall of the neighboring trachea and thereby become technically unresectable (Fig 3).

Malignant tumors should be removed with a margin of uninvolved tissue and all available lymphatics, since extension is most frequently by this route. The treatment of pulmonary cancer is comparable to that of cancer of the breast. And

\*Some of these patients have been previously reported by Ochsolt and Ramey.<sup>1</sup> Only patients whom I have personally bronchoscoped are included in this report.

lary dissection and resection of the lymph nodes are a part of the standard operation for breast neoplasms. For the same reason, pneumonectomy, or removal of the entire organ, is gaining precedence over lobectomy in the treatment of pulmonary cancer. Certain benign tumors, including the so-called "benign adenomas," may be treated by subtotal pulmonary resection. Inspection of the tumor mass bronchoscopically and an actual measurement of the relative position of the tumor in respect to uninvolved bronchi is the best guide to the proper level of resection. Growths

Of the 45 patients who had visible endobronchial tumors on bronchoscopy, 8 presented this type of intrabronchial propagating mass. Of these, 5 tumors were found to be resectable at operation, and 4 of the 5 patients are living and well at the present time. One died suddenly, eight weeks postoperatively, after returning home. No post-mortem examination was made, but clinically he had no evidence of metastatic disease. The relatively benign course of this group of 8 patients is further illustrated by the other 3, who were not resected. One had a lesion involving the

FIGURE 5. Drawings of Normal and Widened Carinas.

*Note the narrow carina on the left, compared with the widened one on the right. The angle formed by the latter is obtuse, owing to spreading of the two main-stem bronchi by a mass of metastatic infracarinal lymph nodes. On palpating the normal carina with the tip of the bronchoscope, it is flexible and quite movable. A carina such as that illustrated on the right is hard and fixed.*

usually invade the wall of the bronchus above the point of obstruction as shown by roentgenography. Thus, it will be found in most cases that a larger rather than a smaller portion of the lung needs to be removed to excise the tumor completely.

#### Gross Pathology

Various configurations are assumed by the intrabronchial portion of pulmonary tumors. Practically all consist of both an intrabronchial and an extrabronchial segment. The semirigid cartilaginous bronchial wall undoubtedly plays a role in the configuration presented. The gross appearance of the tumor has not been found to be an accurate guide to its histologic classification, except that those tumors that are pedunculated and tend to form sessile bodies within the bronchial lumen are apt to be of low-grade malignancy, and therefore particularly suitable for surgical therapy.

carina when first bronchoscoped. This patient died twenty-five months after the onset of symptoms—about twice the average length of survival. The other 2 were explored but not resected, since involved mediastinal lymph nodes were found. One died fourteen months after onset, whereas the other is still living and in comparative good health, three years and five months after the onset of symptoms and over three years since exploration. Of the other 37 patients, there was only 1 who did not have metastases, either clinically or at exploration.

#### Histology

The histology of pulmonary tumors is under a great deal of discussion at the present time, and it is known that some tumors may show varying histologic patterns in different portions of the same tumor. However, the histologic classification of the biopsy specimen from a bronchus is not so important as the determination of whether

or not one is dealing with a malignant lesion. Bronchoscopic biopsy specimens are usually small, and the pathologist is not always able to classify them according to type or grade of malignancy. A diagnosis of malignancy, however, provides a satisfactory working basis on which to plan treatment.

In this series of 47 cases with positive biopsies, the pathologist in 17 cases simply made a diagnosis of carcinoma without any attempt at classification from the biopsy specimen. The others were classified as epidermoid carcinoma in 20, adenocarcinoma in 3, carcinoma simplex in 4, undifferentiated or oat-cell carcinoma in 1 and benign adenoma in 2. In 18 cases in which subsequent surgical procedures or autopsy examination provided the whole specimen, the final diagnosis was the same as the biopsy in 9, or 50 per cent.

Owing to the lack of knowledge of the histopathology of lung tumors in general and the inability to classify the tumor accurately from the biopsy specimen, it seems that for the present the treatment of all carcinomas of the lung should be the same regardless of the histology of the tumor, as revealed by bronchoscopic biopsy.

#### SUMMARY AND CONCLUSIONS

Evidence points to an increase in incidence of cancer of the lung. Approximately 10 per cent of all deaths ascribed to cancer are due to primary lung tumors.

The symptomatology and physiologic disturbances in primary lung tumors are so bizarre and apparently confusing that only a complete investigation, including bronchoscopic study, provides

a satisfactory basis for the determination of therapy.

Bronchoscopy is an easily performed diagnostic procedure without risk to the patient. It should be considered in every case of unexplained pulmonary symptoms.

A series of 62 verified pulmonary tumors is presented. In this group, the diagnosis was established by bronchoscopic biopsy in 46 cases, or 74 per cent.

Primary cancer of the lung should be favorable for surgical treatment in view of the high percentage of positive preoperative biopsies and the ability to make an early diagnosis by bronchoscopic means.

## AUSCULTATION OF THE HEART\*

SAMUEL A. LEVINE, M.D.†

BOSTON

The hearing ear, and the seeing eye,  
The Lord hath made even both of them.

*Proverbs XX: 12.*

AUSCULTATION of the heart is only one of the many methods available for the study of cardiac function and for the detection of cardiac disease. Although it is well for teachers to exhort their students to learn as much as possible by other means, such as the history of the patient, inspection, palpation and percussion, there is no reason to minimize the importance of auscultation or to fail to elicit all possible aid from such a simple procedure. For among all the simple heart findings that one can make, the auscultatory observations are unique and may be regarded as *sui generis*. They cannot easily be confused with those due to other neighboring organs. Furthermore, the use of the stethoscope is easily mastered, and the instrument is available to every physician. In the present era when the economic aspect of the care of the sick is so pressing a matter, any data that can be obtained quickly and without additional cost to the patient are valuable. Moreover, there is certain information that can be obtained only by auscultation.

In performing proper auscultation, one must know what is to be heard. Gross objects are easily seen; minute findings are detected only if one searches carefully. A large goiter cannot escape detection, but a small tophus must be deliberately looked for. Likewise, a loud murmur will not be overlooked, but a telltale gallop rhythm will be heard only by the knowing ear. In a word, one must not only understand how to interpret what one hears but must also be familiar with the various possible peculiar abnormalities that are detectable by auscultation, paying particular attention to different phenomena under different circumstances. The same principle is true throughout medical practice. If a patient's primary complaint is pain in the right loin, which radiates into the groin, one should naturally search for blood in the urine, thinking of a renal calculus. Certainly one would not spend much time looking for a systolic thrill at the base of the heart. On the other hand, if a patient has attacks of syn-

cope and there is a loud systolic murmur over the aortic area, knowing that both might be explained by the presence of aortic stenosis, one should spend a few moments, if necessary, to elicit a systolic thrill, even palpating the chest with the patient sitting up and holding a deep expiration. It is the thoughtful choice of the necessary procedures that spells success in medicine, for no physician can afford to make a so-called "complete" physical examination every time he sees a patient.

Among the various objectives in carrying out intelligent auscultation, the interpretation of the irregularities of the heart is most important. As a result of intensive study and the aid that has come from modern electrocardiography, most of the disturbances in the mechanism of the heart beat can now be detected by simple auscultation. It is a general axiom that the more thoroughly one understands electrocardiography the less one needs it. For this reason alone, it is well for students and practitioners to become familiar with this subject. It is needless in this discussion to take up all the arrhythmias, but I do want to mention some useful points in diagnosis that illustrate how sensitive the ear may be in drawing very fine conclusions from minute auscultatory abnormalities.

When the rhythm of the heart is found to be regular and the rate within normal range, one can usually assume that the mechanism is normal. Like all generalities in medicine, even this has its exceptions. If one had reason to suspect that the mechanism of the heart was disturbed, one might be led to look for some condition like auricular flutter. I recall seeing a young man who complained of palpitation. He appeared to be in good health and showed nothing abnormal on examination. The heart was regular and showed no murmur or enlargement, and the rate was 70. Directly after taking twenty-five hops, the rate was exactly 140 and perfectly regular for a minute or two, following which the rhythm became irregular and gradually returned to the previous level of 70 in a jerky fashion (Fig. 1). This simple observation led to the conclusion that the patient had auricular flutter, that the auricles were beating at a rate of 280, that at first there was a regular 4:1 block with a regular ventricular rate of 70, and that with exercise the block suddenly

\*The Frank N. Wilson Lecture in Cardiology, given at Ann Arbor, Michigan, November 19, 1940.

From the Medical Clinic, Peter Bent Brigham Hospital, and the Department of Medicine, Harvard Medical School, Boston.

†Assistant professor of medicine, Harvard Medical School, physician, Peter Bent Brigham Hospital.

changed to 2:1, resulting in a regular rate of 140. It would otherwise be difficult to explain the exact doubling of the ventricular rate on effort. One might expect the rate to rise to 96, 119 or some other odd figure if the mechanism were normal. Furthermore, a normal heart would accelerate and retard gradually and smoothly following effort and would not become irregular. This simple observation illustrates how detailed a conclusion can be drawn by intelligent auscultation.

The following is another exception in which one

### AURICULAR FLUTTER

FIGURE 1 Response to Effort in Auricular Flutter

*The upper lines indicate the auricular contractions (inaudible), at a rate of 280 throughout the lower lines represent the ventricular responses (audible heart rate). The first set shows a regular ventricular rate of 70; the second set, directly after brief effort, shows a regular ventricular rate of 110; the third set—a continuation of the second—shows irregular slowing to the original slow regular rate of 70.*

might suspect an abnormal mechanism despite a regular normal heart rate. A forty-five-year-old woman, who had had rheumatic fever in childhood, was known to have had mitral stenosis and auricular fibrillation with a grossly irregular heart beat. She had been taking digitalis for some time, and on this particular occasion it was noted that the heart rate was 60 and perfectly regular. The question that came up was whether the auricular fibrillation had changed to normal rhythm. An early apical rumbling diastolic murmur was heard, quite typical of mitral stenosis. On careful auscultation, no murmur whatever could be detected in presystole. This led to the suspicion that auricular fibrillation was still present and that the regular ventricular rate was due to so-called 'digitalis complete heart block'. This suspicion was warranted, because in most cases of mitral stenosis a presystolic murmur is heard if the auricles are contracting and is absent if they are fibrillating.

When the rhythm of the heart is not regular, it is incumbent on the examiner to try to identify the exact type of irregularity. The time has passed

when a physician should be content with the vague observation that the heart is 'slightly irregular' or 'more or less irregular' without trying to determine the type of irregularity. It is just as inadequate an observation as to say that a patient has more or less fever without determining whether it is due to typhoid fever, tuberculosis or pneumonia. A slight irregularity might be the sole clue to a diagnosis, and might lead to correct and effective therapy.

Extrasystoles are very common, occurring both with and without organic heart disease. Owing to the premature contraction of the heart, one hears a quick beat, which may or may not reach the wrist, followed by an abnormally long pause. If the extrasystole is ventricular in origin, this pause is apt to be completely compensatory so that the dominant rhythm is not disturbed, if it is auricular, the pause is not quite so long. This differentiation is not invariable, nor is it a simple matter for the ear to make this distinction. Occasionally it may be useful during auscultation to tap with one's foot in rhythm with the regular beat, not changing the pace, to see if the tap comes exactly on time or after the first beat following the pause. There is another auscultatory finding, however, that may help in distinguishing an auricular from a ventricular extrasystole. An auricular extrasystole sounds a good deal like a normal beat but is heard prematurely. The first heart sound of a ventricular extrasystole has an abnormal clicking quality. The reason for this difference in quality between the two types of premature beats is that the relation between auricular and ventricular systole is different. In the auricular, the normal sequence of auricular and ventricular contraction occurs, whereas in the other the ventricles contract before the auricles. Inasmuch as the position of the auriculoventricular valves at the moment of ventricular contraction greatly influences the quality of the heart sound, one can see that the character of the first heart sound may differ perceptibly in the two types of extrasystoles.

One may ask whether it is of any value to distinguish the various types of premature beats. Generally it is of no great moment, but occasionally it can help in identifying types of paroxysmal rapid heart action. These paroxysms come and go, and the physician may find it difficult to observe the patient while the attack is on. The finding of ventricular extrasystoles during the interparoxysmal periods may point to attacks of ventricular origin, whereas auricular extrasystoles may indicate attacks of auricular origin. Obviously prognosis and treatment may be quite different in the two conditions.

The diagnosis of auricular flutter is generally

very difficult without electrocardiographic aid. In many cases, however, with increasing experience and study, it has become possible to make accurate bedside diagnoses by auscultation. One simple point briefly mentioned above deserves further emphasis. It should be recalled that the sounds result mainly from ventricular contraction. One thereby infers what the auricles are doing. In flutter, the auricles are contracting very rapidly, perfectly regularly and inaudibly. The audible ventricular rate is slower, and may be regular or irregular. When it is regular, the rate must be a simple fraction of the auricular rate (except for the rare cases in which there is a 1:1 response). This means that if the heart rate is 140 the auricular rate must be 280. It cannot be 265 or 311 or any other figure. If the regular ventricular rate is 168, the auricular rate must be 336. Hence, realizing that the auricular rate in an untreated case of flutter is hardly ever under 200 or over 360 and that there is practically always an accompanying heart block, one can draw some simple conclusions. If a regular heart rate is about 198, it cannot be due to flutter, for the auricular rate would have to be 396, which is too rapid or 198, which is too slow. The same reasoning applies to ventricular rates around 210 to 230.

There is another peculiarity that is quite characteristic of auricular flutter. When the mechanism of a regular rapid heart is unknown, vagal

return of the rapid rate, one can be quite sure that it is not a paroxysm of auricular tachycardia, but there is still doubt whether it is a normal sinus tachycardia or auricular flutter. If careful attention is paid to the way in which the previously rapid rate is resumed after the temporary slowing takes place, this differentiation can be made (Fig. 2). In normal sinus tachycardia, the process is smooth and gradual, each beat becoming faster and faster until the original rapid rate returns. In flutter, on the other hand, the recovery of the tachycardia occurs in an irregular or jerky fashion. After the temporary pause or slowing, one or two quick beats may occur, then a slow beat, another quicker beat followed by a somewhat slower one,

FIGURE 2. Response to Carotid-Sinus Pressure. A represents the auricular beats; V, the ventricular beats. The arrows indicate the duration of carotid-sinus pressure. The upper tracing shows gradual slowing from vagal stimulation and a smooth return to the fast rate in a case of normal tachycardia. The lower drawing shows sudden slowing and a jerky return to the original fast rate in a case of auricular flutter. Both started and ended with a regular rate of about 150.

slowing by carotid-sinus pressure may help to reveal the underlying disturbance. Everyone knows that if the attack is abruptly stopped by such a procedure the condition must have been a paroxysm of auricular tachycardia, for no other mechanism will respond in such a fashion. However, if there is temporary slowing with prompt grad-

FIGURE 3. Difference between Frequent Extrasystoles and Auricular Fibrillation.

The upper drawing shows many premature beats (P) preceded by normal beats (N) and followed by compensatory pauses. The lower drawing, which superficially resembles the upper, also shows quick and slow beats, but at one point (X) a slow beat is not preceded by a quick beat. This typifies auricular fibrillation.

until finally the original rapid regular rhythm is resumed. These irregular beats are heard because while the auricles have been very rapid, regular and entirely undisturbed by the vagal stimulation, the degree of auriculoventricular block has been varying. Similar observations may be made if the patient can hold a deep breath or is asked to perform some brief effort. These minute auscultatory changes enable the physician to draw very accurate observations at the bedside.

After a certain amount of training and experience, the diagnosis of auricular fibrillation by auscultation in most cases becomes a fairly simple matter. Occasionally difficulties arise, for it may be confused with auricular flutter when there is a changing degree of block, with frequent extrasystoles or other less common combinations of arrhythmias. In some cases, there is no way of establishing a certain diagnosis without electrocardiographic study. Frequently, however, when confusion arises, correct decisions can be made by the use of simple methods. When for one reason or another the possibility of auricular flutter arises, accelerating the heart rate by having the patient bend up and down in bed several times will give

the answer. In flutter, the rate is apt to become rapid and perfectly regular for a short while, and in fibrillation the gross irregularity will persist. What is more difficult is to distinguish frequent and multiple extrasystoles from auricular fibrillation. Both conditions may have short and long pauses between beats. There may be short runs

#### PAROXYSMAL AURICULAR TACHYCARDIA

#### PAROXYSMAL VENTRICULAR TACHYCARDIA

FIGURE 4. Difference between Paroxysmal Auricular and Paroxysmal Ventricular Tachycardia

The upper drawing shows perfectly regular beats in a case of paroxysmal auricular tachycardia, at a rate of 180. The lower drawing shows slight but definite irregularities in a case of paroxysmal ventricular tachycardia, at the same rate.

of quick beats followed by pauses when there are two or more extrasystoles in quick succession or when they are interpolated. Both may have an appreciable pulse deficit, and may appear to present a total irregularity of the heart. The finding that identifies the arrhythmia as auricular fibrillation is the occurrence of a pause not preceded by a quick beat (Fig. 3). A sudden lengthening of the cycle that follows a quick beat may be due to a compensatory pause after an extrasystole or

FIGURE 5. Changing Quality of Sounds in Ventricular Tachycardia.

The upper lines represent auricular contractions, at a rate of 113; the lower, the ventricular contractions, at a rate of 190. Note the changing time relation between the auricular and ventricular contractions; this changes the quality of the first heart sound.

to fibrillation, but a sudden pause following a beat of normal length will for the most part be due only to auricular fibrillation. After hearing such a sudden lengthening of the heart cycle, one must think back and recollect whether or not the previous cycle was short.

There are characteristic auscultatory findings in most cases of ventricular tachycardia, one of the uncommon but very important cardiac arrhythmias. Unlike paroxysmal auricular tachycardia,

in which the heart beat is almost invariably perfectly regular and the consecutive sounds of identical character, this disturbance is frequently slightly irregular and there may be slight but definite alterations in the intensity or quality of the first heart sound (Figs. 4 and 5). For ten or more beats, the rhythm may be perfectly regular and the heart sounds quite similar in character, just as in auricular tachycardia, and then suddenly for two or three cycles slight but detectable irregularities appear both in time and in the quality of the beats. This peculiarity is due to the changing relation between auricular and ventricular systole that takes place in many cases of ventricular tachycardia; this relation is constant in auricular tachycardia. On rare occasions, I have detected this peculiar alteration in the quality of the heart sounds even when the ventricular rate was perfectly regular, because the auricles were contracting independently and at a different rate. These detailed observations can be made at the bedside by any well-trained physician and may enable him to arrive at a quick decision and institute proper treatment. From a therapeutic point of view, the decision may be a matter of life and death, for ventricular tachycardia generally responds favorably to quinidine therapy and is refractory or aggravated by digitalis.

The diagnosis of the different degrees of heart block can often be recognized by auscultations. In first-degree heart block (simple delayed PR interval), the rhythm of the heart is perfectly regular. This disturbance, therefore, is generally overlooked, unless graphic registration of the heart beat is employed. However, if there is some reason to suspect its presence, as during rheumatic fever, the detection of a definite diminution in the intensity of the first heart sound at the apex points more strongly to this diagnosis. This is particularly true if the intensity of the first heart sound is observed to diminish during the illness. The reversal of this process can also be followed, that is, the gradual return of the previous normal intensity of the first heart sound as the patient is recovering and the conduction time is becoming normal. The reason for the above phenomenon is that the loudness of the first sound is directly related to the PR interval. It is loudest when it is between 0.04 and 0.10 second, normal in intensity between 0.12 and 0.16 second, and gradually becomes fainter when it is 0.20 to 0.28 second or longer. These differences, as mentioned above, probably result because the mitral and tricuspid valves are caught in different positions at the moment of ventricular systole, depending on the time the auricles contract.

Occasionally, in first-degree heart block, one may hear a third heart sound in diastole, resulting in what sounds like a gallop rhythm. This is probably in some way related to the early contraction of the auricle. When it is present and the commoner causes of gallop rhythm, such as hypertensive heart disease and coronary-artery disease, can be satisfactorily dismissed from consideration, it should make one suspect delayed conduction time. These auscultatory findings are of particular importance because there are no other simple means of detecting this condition, and the fact that the heart is perfectly regular otherwise makes the physician entirely oblivious to

FIGURE 6. Bradycardia.

The first drawing (normal bradycardia) shows auricles and ventricles beating slowly and regularly, at a rate of 35. The second (2:1 heart block) shows an auricular rate of 70 and a ventricular rate of 35. The third (complete heart block) shows an auricular rate of 93 and a ventricular rate of 35. In all, there is a regular ventricular rate of 35, but only in the last is there a changing quality of the first heart sound, because of changing relation between the auricular and ventricular systoles.

any disturbance of the mechanism of the heart beat.

Second-degree or partial heart block (dropped beats) is readily recognized because the loss of an entire heart cycle is easily heard on auscultation. It must not be expected that the pause will be quite so long as two normal heart cycles, because the last beat before the pause is accompanied by a long PR interval and the one after the pause by a much shorter PR interval. In sinoauricular block, a far rarer condition, this pause is much likelier to be exactly equal to two heart cycles. Partial heart block must not be confused with extrasystoles. In both, the peripheral pulse may intermit for an entire cycle, but with extrasystoles a premature beat ought to be heard over the precordium during this interval, and in block

no such beat will be present. The difficulty is that premature beats are very rarely inaudible and in auriculoventricular block a faint auricular sound may resemble an extrasystole. In these cases, one is entirely dependent on electrocardiography.

There is one auscultatory sign that is quite pathognomonic of complete heart block. Apart from the slow, generally regular beat of 30 to 40, one should pay particular attention to the quality of the first heart sound in different cycles. If the heart is slow at a rate of about 35 to 40 and regular, it can be due to complete block, to a regularly recurring 2:1 block or even to a normal bradycardia (Fig. 6). In the last, there may even be no heart disease whatever. The differentiation between these conditions may therefore be quite important: If there is complete dissociation (except for the rare cases in which auricular fibrillation is also present), the first heart sound varies in intensity or quality in different cycles, sometimes suddenly becoming booming or muffled or reduplicated. Just as in ventricular tachycardia, this is owing to the changing relation between the time of auricular and ventricular systole. When the slow rate is due to 2:1 block or to a normal bradycardia, the sounds are all alike. It must be borne in mind that hearing auricular beats during the long ventricular pauses, although a common finding in heart block, does not mean that the block is complete. It is the peculiarity of the first heart sound above mentioned that identifies the condition as complete dissociation.

Apart from the irregularities of the heart, the quality of the sounds may have significance. Distant heart sounds need not indicate heart disease, since they often result from pulmonary emphysema or a thick chest wall. In the absence of these or other obvious causes, and especially if the heart sounds are known to have been of normal intensity shortly before, a marked diminution in the intensity of both heart sounds occurs in some cases of acute coronary thrombosis and in extensive pericardial effusion. Apart from these considerations, so-called "weak heart sounds" have little clinical value. The term is often misleading, for the connotation that the heart is weak need not be true.

Accentuation of the first heart sound may have considerable diagnostic value. It is frequently an early evidence of developing mitral stenosis and should lead the examiner to search with greater care for the short presystolic or mid-diastolic murmur that characterizes mitral stenosis. Furthermore, a snapping first heart sound may be the first clue that the patient has hyperthyroidism. It is obvious that in the classic case of thyrotoxicosis

other features, like exophthalmos, enlarged thyroid gland, a typical history of nervousness, palpitation and loss of appetite, readily reveal the true nature of the underlying morbid process. In some of the obscure cases, however, many of these points are lacking, and one may be led to the diagnosis by auscultation of the heart. Accentuation of the first heart sound may also be found in nervous patients, in hypertension, in anemia and in some fevers, especially rheumatic fever.

There is one condition that I especially wish to mention because it has only recently been recognized as a clinical entity and is one in which the first sound is also distinctly accentuated. It is the syndrome of short PR interval with curves resembling bundle-branch block occurring in patients prone to have paroxysms of rapid heart action. It was first called to attention as a clinical unit by Wolff, Parkinson and White,<sup>1</sup> although Wilson<sup>2</sup> reported an isolated case of this sort many years before. These patients, who apparently show no evidence of organic heart disease, are subject to attacks of palpitation and show an unusually short PR interval when the heart rate and rhythm are normal. The only method suggesting the presence of the abnormal mechanism before electrocardiograms are taken is the detection of an unusually accentuated first heart sound. I mention this because only recently I had such an experience, and the auscultatory suspicion was validated by electrocardiographic study.

In the diagnosis of acute pericarditis, one is almost entirely dependent on auscultation. There is nothing in the history or in other methods of examination that is so helpful diagnostically or in fact that may throw any light whatever on the diagnosis. Unless one hears the telltale to-and-fro pericardial friction rub, one is generally unable to make the diagnosis of acute pericarditis. Inasmuch as this sign is likely to be transient and may last only a day or so, frequent auscultation is necessary. Occasionally, it is heard only if the patient sits up or bends forward. Apart from its specific diagnostic value, its detection may help in identifying one illness as being rheumatic, another as acute coronary thrombosis, and so on.

Gallop rhythm is a purely auscultatory phenomenon. Although in some cases there are other associated phenomena, such as bundle-branch block, a doubling of the apex impulse and pulsus alternans, the quality of the heart sounds alone has a specific connotation. Care must be taken to differentiate a diastolic from a systolic gallop. The former almost invariably signifies grave heart dis-

ease; the latter is found in structurally normal hearts. The differentiation may be facilitated by the following procedure. When a so-called "normal" or midsystolic gallop is present, it is heard at the apex, and on rhythmically moving the stethoscope toward the base of the heart, one finds that the abnormal third sound gradually disappears. It should also be noted that the sound to disappear is the middle one of the three, leaving the two normal heart sounds that are customarily heard at the base of the heart. It is also of some clinical interest that the common diastolic gallop rhythm that generally indicates a grave prognosis is extremely rare in auricular fibrillation or flutter. Occasionally, this antagonism is indirectly helpful in diagnosis, when a gallop disappears and a new rhythm is established. Finally, a word of caution may be appropriate concerning the confusion between cases with gallop rhythm and those showing a normal third heart sound or those in which a third sound in mid-diastole proves to be the early evidence of developing mitral stenosis. Experience and mature judgment are required to make these differentiations.

Pulsus alternans is a peculiarity of the peripheral pulse in which alternate regular beats are strong and weak. It connotes grave heart-muscle disease. Not infrequently, this may be detected on auscultation of the heart itself, when the heart sounds or an accompanying systolic murmur are found to alternate in intensity.

There are other extremely rare cases in which peculiar sounds are heard over the precordium. A tinkling or splashing sound with each heart beat suggests both air and fluid in the pericardial sac or a diaphragmatic hernia with the heart pulsating against the stomach contents. Recently Hamman<sup>3</sup> described unusual crunching sounds with the heart beats in acute mediastinal emphysema, a condition that is easily confused with acute coronary thrombosis. These are all very rare conditions, but they are recognized mainly through auscultation.

Finally, the subject of cardiac murmurs must be considered. This is not the occasion to discuss the significance or interpretation of specific murmurs. I do wish to emphasize that the detection and proper interpretation of murmurs is a very important function of the clinician. It is true that the question whether a heart is failing is not dependent on the presence or absence of murmurs. Nor may the presence or absence of murmurs decide whether the symptoms of which a patient complains are due to the heart. But very often the pres-

ence or absence of murmurs determines whether there is organic heart disease. No simple method of diagnosis other than auscultation is valid in chronic valvular disease. Very often, the decision whether the heart is perfectly normal or whether there is early aortic insufficiency or mitral stenosis can be made only when a faint diastolic blow along the left sternal border or a short presystolic murmur at the apical region is heard. In some cases, the diagnosis depends entirely on these auscultatory findings, for electrocardiograms and roentgenograms may fail to reveal significant abnormalities. When it is realized that patients have compensated organic valvular disease for many more years than they have heart failure and that they often desire to know whether heart disease of any sort exists, this subject must be of considerable importance.

As a corollary of the above, it is well for physicians to develop confidence in detecting cardiac murmurs, for if one can be certain that there are no murmurs whatever it makes it extremely unlikely that there is any valvular disease. This question is of significance for patients who have recovered from rheumatic fever or chorea. When they are seen years later, the complete absence of murmurs means that the heart has entirely escaped permanent injury and they may be regarded as normal, unless a new infection later develops. While any murmur is present, although they may yet carry on normally, they are subject to the hazard of progressive stenosis of the valves and subsequent congestive failure or superimposed bacterial endocarditis. In other words, it is my opinion that apart from the acute stages of rheumatic infection, when the involvement of the heart muscle is paramount, the subsequent health of the patient depends entirely on involvement of the

valves. The development of chronic heart failure in rheumatic valvular disease is directly or indirectly the result of the mechanical insufficiency or constriction of the valves and is not dependent on any peculiarity of the heart muscle. It may be considered that the myocardium recovers completely or that at least its involvement is insignificant in determining the ultimate outcome in most patients with rheumatic heart disease who do not succumb early, during the active stage of infection. This point of view is emphasized to counteract a prevailing concept that places all importance on the myocardium in determining the development of heart failure. Although the myocardium is of primary significance in hypertensive heart disease and in coronary-artery disease, I believe that it plays a minor role in chronic rheumatic valvular disease.

There are many more valuable diagnostic points to be elicited by auscultation than I have mentioned. Some have been deliberately omitted because they are common knowledge, others because of my own limitations. There remains much that will yet be learned by further study. If I appear to have overemphasized the use of auscultation, it must be laid to my interest in this subject. It has one great advantage, however: the procedure is valuable and simple, and the data are inexpensively obtained and available to all students and practitioners. If for no other reason, it merits serious consideration.

# POLLEN AND MOLD SURVEY OF SOUTHEASTERN NEW ENGLAND—1940

HENRY N PRATT, MD \* ABRAHAM COLMES, MD,† JOHN FROXIER, MD,‡  
J EVARTS GREENE, MD § FRANCIS H CHAFFEE, MD,|| AND  
WILLIAMS B CLAPP, MD ||

THERE are few reports on the seasonal contamination of the air in New England with the pollens and molds that are proved excitants of asthma and hay fever. Rackemann and Smith<sup>1</sup> Durham<sup>2-4</sup> and Pratt<sup>5-6</sup> have each recorded pollen or mold surveys from single stations in Boston. Sylvester and Durham<sup>7</sup> have presented a relatively complete study of the ragweed season in Maine, demonstrating the diminishing amount of ragweed pollen found in the air as one progresses north from Portland. In view of the paucity of such reports, it was considered advisable to make a more thorough co-operative study, with special reference to the variation of daily counts from adjacent stations within the City of Boston and to compare these with counts at Worcester, Providence and suburban Boston.

## METHOD

Six stations were established, brief descriptions of which follow:

**Station 1 Boston** The roof of the five story main building of the Children's Hospital, Longwood Avenue, exposed to the wind from all directions.

**Station 2 Boston** A third floor window frame at the Beth Israel Hospital, Brookline Avenue, exposed to the wind from the northeast, east and southeast.

**Station 3 Boston** The roof of the five story Lahey Clinic building on Commonwealth Avenue, exposed to the wind from all directions but especially from the east and west.

**Station 4 Newton Center** Six inches above the ground, 25 feet from a house in a suburban district where the houses are 50 to 100 feet from each other, exposed to the wind from all directions, but especially from the southwest, southeast and northwest.

**Station 5 Providence, Rhode Island** A second story porch in the residential district exposed to the wind from the northeast, east, southeast and south.

**Station 6 Worcester, Massachusetts** The roof of the three story Memorial Hospital in a thickly settled district, exposed to the wind from all directions.

Stations 1, 2 and 3 are on the western edge of Boston and within a mile of each other. The area is characterized by apartment houses, vacant lots and shade trees.

At each of the six stations, slides were exposed under a cover 2 to 3 feet square and 6 to 8 inches above the slide. The slides were open to the weather. Between 8 and 9 o'clock each morning, a slide coated with glycerin jelly was exposed at each station and collected twenty four hours later. Over week ends and on holidays, slides were exposed for forty eight hours. The pollen grains and *Alternaria* spores falling on 18 square centimeters were identified and counted. The slides were stained with Calberla's fluid to assist in identification of the pollen grains. In addition, the number of colonies of *Alternaria* growing on a thin layer of Sabouraud's medium in Petri dishes exposed to the outside air for a half hour three times weekly was determined. Taking into account time and area, the slide counts should theoretically be about 40 per cent higher than the plate counts.

Charts were constructed in which the number of pollen grains or *Alternaria* spores falling on 18 square centimeters in twenty four hours is represented as the ordinate and the dates as the abscissa. Where slides were exposed for forty eight hours, the counts were divided by two and charted as if for individual days.

## RESULTS AND COMMENT

Figures 1, 2, 3 and 4 represent the pollen counts for the average of the three Boston stations and for Newton Center, Worcester and Providence respectively. All show the same variations with fairly well demarcated tree, grass and weed seasons. Table I itemizes the actual dates when appreciable amounts of pollen were in the air at each station for the 1940 season. It will be observed that the dates are remarkably similar for each station except for the end of the grass season, which terminated gradually during July. The weed pollens stopped abruptly with frost on September 24.

A comparison of Figure 1 for the Boston stations and Figure 2 for Newton Center demonstrates the difference between city and suburban

weed pollens were much more abundant in the suburban area.

Figure 5 represents the pollen counts at two

FIGURE 1. Average Pollen Counts at Three Boston Stations.

FIGURE 2. Average Pollen Counts at Newton Center.

areas. In both places, the tree counts are of the same order of magnitude, because shade trees are numerous in the parts of the city studied. However, it is not surprising to find that grass and

Boston stations only a few hundred yards apart. Failure of the pollen peaks to be consistently superimposed demonstrates that local variations in vegetation and wind currents may grossly affect

the counts. This suggests one reason why all hay-fever patients do not have severe symptoms on the same days.

and asthma, and yet when pollen counts are made by the gravity method, the weeds appear to be the least important, if quantity is any criterion.

FIGURE 3 Average Pollen Counts at Worcester.

FIGURE 4 Average Pollen Counts at Providence.

It has been recognized from clinical evidence that the weed pollens from late August to frost are the commonest seasonal excitants of hay fever

This paradox is explained when the number of pollen grains per cubic yard of air is calculated. Stokes's law for falling bodies, as adapted by

Scheppegregg<sup>8</sup> and corrected by Cocke,<sup>9</sup> has been experimentally shown by Cocke<sup>10</sup> to be accurate for pollen grains if the spiculated surface of the weed pollens is taken into account. Utilizing Cocke's tables and assuming that Wodehouse's<sup>11</sup> figures for pollen size are correct, the average number

fore probably the most important clinically. There were moderate amounts of poplar and maple pollen and a little alder, ash and beech. Pine pollen frequently appeared on the slides in fairly large amounts, but since pine pollen contains no atopic excitant,<sup>12</sup> it was omitted from the charts

TABLE 1. Pollens During 1940 Season.

STATION	TREES	GRASSES	WEEDS
Three Boston stations	April 22-May 27	June 5-late July	August 20-September 24
Newton Center	April 27-May 30	June 6-July 8	August 26-September 24
Worcester	April 26-May 22	May 27-late July	August 19-September 24
Providence .	April 19-May 28	June 5-July 23	August 28-September 10

of pollen grains per cubic yard of air for each day was calculated for Newton Center and is shown in Figure 6. Because of its small size and spiculated surface, the ragweed granule settles out of the air much more slowly than the larger, smooth, tree and grass grains. Figure 6 gives a clearer

and calculations. At two stations where linden trees were in the neighborhood, a small quantity of pollen was recovered in July, but linden is a flowering tree and is not generally considered to be a cause of hay fever or asthma.<sup>11</sup> It, too, was omitted from the charts. Occasional grains of

FIGURE 5. Average Pollen Counts at Two Boston Stations.

picture of the clinical significance of the three pollen seasons. Taking thirty-one consecutive days in each of the three seasons and calculating the average contamination of the air per cubic yard for this period for each season, the results are: trees 415, grasses 250 and weeds 555.

Among the trees, elm, birch and oak were by far the most abundant pollinators and are there-

unidentified pollen were also disregarded.

There are five common grasses in New England: June, orchard, sweet vernal, red top and timothy. The pollens of these grasses and of plantain are very difficult to differentiate, and therefore no effort was made to separate them. Furthermore Rackemann and Wagner<sup>13</sup> have shown by desensitization of passively sensitized skin sites

that although no one of the three commonest grasses (timothy, orchard and red top) invariably desensitizes to the two others, crossed reactions

out the clinical observation of the overwhelming consequence of ragweed in fall hay fever.

Among the mold spores producing respiratory

FIGURE 6. Average Pollen Counts at Newton Center.

FIGURE 7. Average *Alternaria* Counts at Two Boston Stations, Newton and Worcester.

between the different species are very common.

The weed pollens consisted of ragweed (92 per cent), goldenrod (4 per cent), cocklebur (3.2 per cent) and wormwood (0.8 per cent). This bears

allergy, *Alternaria* is the commonest.<sup>6</sup> Figure 7 summarizes the results for the four stations at which exposures of slides and plates were made regularly (two Boston stations, Newton Center

and Worcester). To produce more consistent curves, the chart was constructed by adding the daily slide counts of the four stations and graphing the daily total as a solid line. The sum of the plate counts is represented as an interrupted line. Therefore, the curves are four times higher than they would be for a single station. Although the two curves do not superimpose, they are both of the same order of magnitude, the slide counts averaging slightly higher, and show the same seasonal fluctuation. The total counts for the season from the four stations gave essentially the same results except that the total for Newton Center was somewhat greater than that for the city.

The *Alternaria* season does not have such definite time limits as the pollen seasons. As shown previously,<sup>5, 6</sup> *Alternaria* can be cultured from the air in Boston throughout the entire year, but the heaviest contamination comes with the onset of warm weather, in July, when the grass counts are dwindling. The season reaches its peak with the weeds but persists into November long after ragweed pollen has left the air.

It will be noted that the counts of *Alternaria* here recorded are low compared with the pollen counts. However, the spores probably settle out of the air considerably more slowly than pollen because they are smaller and irregular in shape. Stokes's law does not apply to the calculation of their rate of fall, since they are not spherical. It seems probable that the per cubic yard contamination of the air with *Alternaria* spores is not much less than that of ragweed pollen in late August and early September.

## SUMMARY

A survey of the pollens producing hay fever in southeastern New England shows three clearly defined seasons: trees from April 19 to May 30, grasses from early June to mid-July, and weeds from August 20 to late September. The *Alternaria* spore season overlaps the grass and weed seasons and persists later into the autumn.

Grass and weed pollens are more abundant in suburban areas than in the city, whereas tree pollen is equally plentiful in town and city because of the numerous shade trees in the areas of the city studied.

Failure of pollen peaks from neighboring stations to be superimposed consistently demonstrates the effect of local vegetation and wind currents.

## MEDICAL PROGRESS

### PHYSICAL THERAPY

ARTHUR L. WATKINS, MD†

BOSTON

ONE of the outstanding events in physical medicine during the last two years was the publication of an excellent textbook by Krusen.<sup>1</sup> There has long been a need for a reference book to which the student or practicing physician could turn for sound and detailed information on the practical aspects of physical therapeutics. Krusen is an authority on the subject, and has had unusually large experience in clinical application and investigative work. In addition to comprehensive presentations of the subjects of heat, light and electrotherapy, he has included the technic and indications for the use of hydrotherapy, massage and exercise—measures that have received little acclaim recently because of enthusiasm concerning electrical apparatus, which actually have only a small role in physical therapy. The present knowledge of the physical and physiologic principles involved has been summarized, with extensive references. The illustrations and explanations of simple measures that may be used in the home are especially valuable.

Hypothermia has recently been found to have more new useful applications than any other physical measure. Many investigative studies have dealt with the physiologic changes and therapeutic effects of the reduction of general body temperature and the local use of cold. The present status of this therapy has been reviewed by Talbot.<sup>2</sup>

Recent developments in the use of the majority of other physical agents are presented in relation to the different medical specialties.

### MEDICINE

In the treatment of rheumatoid arthritis and degenerative joint disease, physical measures continue to have a significant role. In these conditions with a tendency to chronicity, simple procedures that can be carried out in the home should be emphasized. Krusen<sup>3</sup> has outlined specific instructions for the use of homemade brakers, clamp lamps, hot paraffin packs, whirlpool baths and contrast baths. Massage, when skillfully adminis-

tered on nonacute joints, is beneficial, and a lay person with proper instruction may learn simple techniques that are of value in improving local circulation and in relieving muscle spasm. It is recognized that training in body mechanics is effective in preventing undue strain and trauma on diseased joints.<sup>4</sup> Postural and specific graded exercises for increasing joint range and muscle power are probably of more benefit than any other physical measure when properly supervised.<sup>5</sup> Diathermy,<sup>6</sup> cabinet baths and more elaborate types of treatment have a place in hospital departments.<sup>7</sup> However, results of fever therapy in rheumatoid arthritis and osteoarthritis have been disappointing.<sup>8</sup> Iontophoresis with histamine and acetyl beta methylcholine chloride has given encouraging results,<sup>9-12</sup> but has not replaced other simpler agents for symptomatic relief. Neurologic symptoms may accompany cervical degenerative arthritis, and much benefit may be obtained by heat, massage, traction, manipulation and posture training.<sup>13</sup> The temporomandibular joint is frequently involved and often is not treated adequately. Bayles and Russell<sup>14</sup> brought out the necessity of complete rest and local heat during the acute stages, with mild gum-chewing exercises later. Coccygodynia, when caused by spasm of the levator ani, coccygeus and piriformis muscles, has frequently been relieved by internal massage, according to the experience of Krusen and Basom.<sup>15</sup> They also reported success from firm massage over the fibrous nodules, in addition to local heat and stretching exercises, in the treatment of fibrositis.

Short wave diathermy has been reported as curing lung abscess in 85 of 123 cases in the literature, as reviewed by Brugsch and Pratt.<sup>16</sup> In 8 cases, however, applications for ten to forty five minutes were given without effecting a cure. Only 2 of these cases were acute, and this method of treatment may deserve further trial in the acute stage. In spite of the steadily improving results of chemotherapy for pneumonia, diathermy is still thought to be a valuable adjunct in treatment, since it decreases cyanosis by improving pulmonary circulation.<sup>17</sup> Overdosage is to be avoided because of the possible edema.

In the management of cardiac conditions during convalescence, a carefully supervised, indi-

All articles in this series will be published in book form in the current volume of *Medical Progress*, Jan. 1940 (Springfield, Ill. no. 5; Charles C. Thomas Company, 1941; \$4.00).

\*From the Department of Physical Therapy, Massachusetts General Hospital.

†Assistant in Medicine, Harvard Medical School; Director of Physical Therapy, Massachusetts General Hospital.

vidual program of physical measures is beneficial.<sup>18</sup> This may consist, at first, in gentle stroking and passive motion of the extremities, followed later by graded active exercise to improve peripheral circulatory efficiency.

### GENERAL SURGERY

The aim of physical therapy in traumatic conditions is to shorten convalescence and rehabilitate the patient. In fractures, the early use of measures to soften or eliminate induration, diminish swelling, and lessen redness and heat ensures early function.<sup>19</sup> Elevation, gentle stroking, sedative massage, prolonged mild heat and assisted active exercise without pain may accomplish this.<sup>20-24</sup> The frequency of treatments is of some economic importance. Butler<sup>25</sup> has recommended daily treatments so long as there is progress, as measured by careful observations. Occupational therapy may then take over and speed return to work. Contusions of muscles may lead to myositis ossificans and prolonged disability. Preventive measures should be used in the early stages to control hemorrhage by cold applications and a compression bandage; massage on severe tender contusions should be avoided. Later, heat aids in the absorption of the hematoma.<sup>26</sup> Injuries involving tendons and nerves, particularly of the hand, should be splinted in a position of physiologic rest, care being taken to avoid tension on sutures.<sup>27</sup> Experimental studies of the tensile strength of healing tendons have revealed that motion should not be started until after sixteen days; it should then be restricted for two weeks more, when free active motion is safe.<sup>28</sup>

In the treatment of peripheral vascular disease, the value of alternate positive and negative pressures, by means of a leg boot and intermittent venous occlusion, appears to be limited.<sup>29</sup> The careless use of local heat, particularly diathermy, is dangerous, since the metabolic requirements may be increased beyond the circulatory capacity and gangrene may develop.<sup>30</sup> When heat is indicated, either a thermoregulated cradle or reflex heating by warming the upper extremities or by applying diathermy over the sacral areas is desirable.<sup>31, 32</sup> Iontophoresis with acetyl-beta-methylcholine chloride does not replace surgical measures for varicose and post-thrombophlebitic ulcers, but after simpler methods have failed, some discomfort may be relieved by this means and healing promoted.<sup>33, 34</sup> Buerger's exercises continue to be a valuable adjunct in treatment when carefully prescribed,<sup>35</sup> and the oscillating bed tends to effect the same results when active exercises are impossible.<sup>36</sup>

Since the advent of extensive chemotherapy,

local measures have assumed less significance in the treatment of genitourinary infections. Diathermy, however, is still useful for symptomatic improvement in chronic prostatitis and pelvic inflammatory disease.<sup>37</sup>

A major part of treatment following thoracoplasty is the prevention of scoliosis and limited painful motion of the shoulder girdle and arm. A carefully graded set of exercises with skillful supervision gives gratifying results.<sup>38</sup>

The sterilization of air in the operating room by means of ultraviolet radiation has been studied, and methods have been developed whereby it is claimed that contamination from unsterile air can be practically eliminated.<sup>39-42</sup> Similar methods have been valuable in reducing the incidence of respiratory-tract infections on hospital wards.<sup>43-45</sup>

### ORTHOPEDIC SURGERY

The problem of chronic backache and sciatic pain has not been solved, as indicated by the numerous publications recommending different treatments. A recent symposium<sup>46</sup> on diagnosis and treatment has been published and contains much valuable information concerning the relation to backache of posture, visceral disease, fractures and other trauma, faulty mechanics and inflammatory processes. Surgical and conservative measures in treatment are discussed. Kuhns<sup>47</sup> reports the relief of sciatic pain and low-back disability in 771 of 1000 cases by means of rest on a flat bed with hips flexed for ten days and daily application of heat, followed by graded exercises and support when the patient is ambulatory. The different physical measures indicated in backache from various causes include traction, manipulation, special stretching and postural exercises, massage, particularly firm massage in fibrositis, and local application of heat.<sup>48</sup> Corsets are frequently helpful, and the proper types to be used have been discussed by Ober.<sup>49</sup>

A specific exercise program is of distinct value in the treatment of scoliosis. Colonna and vom Saal<sup>50</sup> found that 30 per cent of 500 cases of poliomyelitis developed scoliosis. The presence of asymmetrical paralysis and inadequate support were important factors in its development. Muscle-training and chest-expansion exercises were helpful, but spinal fusion was usually indicated in the presence of moderate and severe deformity. Conservative treatment in carefully selected cases has been successful in Steindler's<sup>51</sup> experience. The lumbar and cervicothoracic sections of the spine were limbered up to promote derotation and the development of countercurves to establish compensation. Adequate musculature was essential for success. In those cases requiring fusion, the

physical therapists are called on for special limbering and manipulative treatments prior to operation.<sup>52, 53</sup>

In deformity of the back due to juvenile kyphosis, physical measures are relied on almost exclusively in treatment. These consist in support, rest, local heat, light relaxing massage and corrective exercises of graded intensity.<sup>54</sup> Wheeldon<sup>55</sup> has suggested that contracted hamstring muscles may have a role in the production of poor posture and juvenile kyphosis. Fifty per cent of his cases were improved by passive hamstring stretching and remained improved. Twenty-five per cent tended to recur when the exercises were stopped. The remainder were unaffected by exercises. In this last group, he has had success by resection of the hamstring muscles.

Orthopedists and physical therapists have frequently expressed the advantages of good posture. Joplin<sup>56</sup> has applied the principles of posture in occupational therapy, which is a timely and worthwhile contribution. Most of the concepts of postural instruction are based on empirical evidence. A metabolic study, however, showed that the energy expenditure of standing was very small, and the sense of fatigue associated with motionless vertical posture may be due to cerebral anemia, which can be overcome by sway and relaxed stance.<sup>57</sup>

The chief development in the treatment of infantile paralysis that commands interest at present is the so-called "Kenny method." Briefly, this consists in nearly continuous daily hot fomentations during the acute stages to relax spasm, no splinting, early passive and active exercises without pain, and special muscle re-education, concentrating on the insertion of muscles, with attention to body mechanics. Kenny's theory is that the important features of acute poliomyelitis are muscle spasm, inco-ordination due to pain and substitution of muscle function, and mental alienation, because of which the patient forgets normal muscle performance or loses the idea of making muscles contract. Complete evaluation of this treatment is not possible, according to preliminary reports.<sup>58</sup> Certainly, quick recoveries have been observed, but it is too early to determine end results. Levin<sup>59</sup> has written a splendid book covering the many aspects of diagnosis and treatment of this disease.

The treatment of painful shoulders caused by bursitis is still unsatisfactory in spite of reports of success with novocain injections, saline irrigations, operative removal of calcium deposits, manipulation, rest, local heat, exercise and large doses of ammonium chloride.<sup>60-67</sup> A carefully

controlled study of these various methods is needed for proper evaluation.

Foot disabilities are common and are frequently due to mechanical strain. Training in proper use of the feet, special foot exercises, posture correction, contrast baths and proper shoes are measures recommended in prevention and treatment.<sup>68, 69</sup>

#### NEUROLOGY AND PSYCHIATRY

The most interesting recent development in the treatment of mental disease by physical agents is the use of electric-shock therapy. The first clinical work was done in the Rome clinic by Bini<sup>70</sup> in 1938 and by others.<sup>71</sup> The advantages claimed for this method over other types of shock therapy are simplicity, as compared with intravenous medication in overactive patients, immediate loss of consciousness, with amnesia for the whole treatment, and a low incidence of complications, with few fractures and systemic reactions. The apparatus used in this country by Myerson has been described by Feldman and Davis.<sup>72</sup> The current source is a 60-cycle alternating current with a controlled range of voltage from 50 to 130 and a milliamperage from 50 to 750. Metal electrodes, with electrode paste, are attached to both temporal regions with a head band. The average patient required 70 volts at 350 to 500 milliamperes for 0.1 second to produce a convulsion.

Meggendorfer<sup>73</sup> treated 40 patients with schizophrenia, with very good results in 10 and temporary improvement in 10 more; the others were not benefited. All eight patients with manic-depressive psychosis were improved. Gonda<sup>74</sup> reported 58 per cent remissions in 29 patients with schizophrenia, and 87 per cent recovery in 8 patients with manic-depressive psychosis. Myerson<sup>75</sup> states that the psychoses of choice for treatment are the marked continuous depressions, and that the treatments may be given in the home or office. In schizophrenia, this method has the same general value as the use of Metrazol, and the indications for treatment are the same. No neurologic sequelae have been observed, but Gonda reported the fracture of both humeri in 1 case. Precautions must be taken against fractures, as with any convulsive therapy, and the equipment must be tested before each treatment. The changes in the human central nervous system are unknown, since there have been no deaths. Bini,<sup>70</sup> however, has reported changes in animals that were in some cases irreversible, although not described in detail. Other observers have stated that the changes in animals were not so severe as those found after insulin hypoglycemia.<sup>71</sup>

Infantile cerebral palsy occurs in about 7 hirths

per 100,000 population a year and presents a problem in treatment. Spastic, athetoid and ataxic cases should be differentiated, since the treatment varies accordingly. Institutions where muscle re-education and schooling can be carried out together are most effective. Home therapy is very satisfactory in some cases but must be individualized, and the nature of the disorder and the personality must be understood by the family. The program of treatment consists essentially in special relaxation and co-ordination exercises, which must be persisted in daily and combined with occupation to form new habit patterns. Several recent publications<sup>76-82</sup> have been found helpful by parents and workers in the field.

The exact value of electrical stimulation in peripheral-nerve lesions to lessen atrophy and promote return of function is still problematical. In experiments on sciatic section in monkeys<sup>83</sup> and dogs,<sup>84</sup> it has been found that the degree of regeneration of peripheral nerve fibers and the atrophy and degeneration of denervated muscles are uninfluenced by physical therapeutic methods, including electrical stimulation. Massage and passive movement seemed most beneficial in securing maximum return of function, provided there was adequate splinting. Fischer,<sup>85</sup> however, showed in rat experiments that twelve to twenty minutes of intensive electrical stimulation produced a training effect in denervated muscles that lessened the degree of atrophy. Clinical experience has led most observers to consider electrical treatments beneficial in facial-nerve paralysis, but large series of cases and controls will be necessary to obtain more objective evidence of the value of electrical stimulation.<sup>86</sup>

#### DERMATOLOGY

The dermatologist is particularly interested in ultraviolet irradiation, because so many skin diseases have been given this therapy with both beneficial and deleterious results.<sup>87</sup> Blum<sup>88</sup> has recently made an outstanding contribution to the literature on the subject of light in relation to medicine. He carefully defined photodynamic action and described methods of investigation that should lead to more accurate studies in the future. Diseases due to light are considered in a separate section. It is essential that clinicians be aware of these conditions, since ultraviolet irradiation may be extremely dangerous, as in lupus erythematosus. Of late, the photosensitizing action of the sulfonamides has been frequently reported.<sup>89-91</sup> Sulfanilamide in high concentration sensitizes human skin to irradiation below 3200 Angstrom units, producing severe sunburn. This is not photodynamic action, and porphyrins are

not involved, but it probably represents an increased sunburn reaction. Patients receiving sulfonamides should therefore not be exposed to sunshine or ultraviolet lamps. This photosensitizing action of sulfanilamide has been used in the treatment of psoriasis to enhance the effect of ultraviolet irradiation, but is not recommended routinely because of the potential dangers.<sup>92</sup>

Several reports have appeared on the successful treatment of fungous infection of the hands and feet by copper iontophoresis. Hoechstetter<sup>93</sup> treated 18 cases, with healing in 16, giving five to nine treatments weekly, or twice a week when the infection was severe. Equally good results were obtained by Haggard, Strauss and Greenberg.<sup>94</sup>

#### OTOLARYNGOLOGY

Local heat in various forms gives some symptomatic relief from upper respiratory-tract infections. A simple infrared lamp is quite effective for this purpose. Short-wave diathermy has been used extensively for sinusitis, but does not effect a cure.<sup>95</sup> Better results are obtained in acute cases than in chronic ones, but postoperative results are disappointing. In the treatment of gingivitis, parodontosis and postextraction pain, short-wave diathermy gave relief in all 64 of Kobak's<sup>96</sup> patients. Ion transfer (iontophoresis), using zinc salts for hay fever, vasomotor rhinitis and chronic otorrhea, has not brought the cures first hoped for. Evidence for proper selection of cases awaits further investigation.<sup>97</sup>

#### FEVER THERAPY

Artificial fever continues to have a role in the treatment of syphilis, gonorrhea and chorea. The methods of production and effects have recently been summarized.<sup>98</sup> Results and hazards are about equal with inductive heating, hot moist air and hot sprays of water.

In general paresis, results have been slightly better with artificial fever than with malaria.<sup>99</sup> Solomon, Kopp and Rose<sup>100</sup> have tried the effect of increasing the temperature swing during a six-hour period by first reducing the temperature to 90°F. under Pentothal anesthesia with ice packs, and then inducing a fever of 104 to 105°F. They have as yet made no conclusions of its value.

The sulfonamides have subordinated fever therapy in the treatment of gonorrhea, but the percentage of resistant cases has been reported from 10 to 20.<sup>101-103</sup> These results are about the same as those of fever alone. The combined use of sulfanilamide and fever, however, has given nearly 100 per cent cures.<sup>104-107</sup> Medication for eighteen to forty-eight hours prior to fever therapy has been recommended. A single ten-hour fever at

106 to 107°F has then been sufficient to obtain negative cultures

Good results of treatment of eborca by artificial fever continue to appear<sup>108-110</sup> Short sessions (two and a half to three hours) at 104 to 105°F are repeated daily or on alternate days for a total of about twenty to thirty hours of fever as the usual routine Bennett and Hochstra<sup>110</sup> had excellent responses in all 17 of their cases, Elkins and Krusen<sup>109</sup> reported only a single failure in 20 cases adequately treated

Hyde<sup>111</sup> has tried short (one hour or less) and mild (up to 103°F) fevers in allergic diseases with interesting results Thirty two patients were treated, with improvement in 75 per cent of the asthma cases and 81 per cent of the hay fever cases

An increase in temperature from 98 to 103°F has been shown to increase the bacteriostatic power of sulfanilamide about one hundred times<sup>112</sup> With this in mind, combined fever and chemotherapy has been tried in subacute bacterial endocarditis Bierman and Bachr<sup>113</sup> treated 16 cases with 2 cures, two years and ten months, respectively, after treatment Krusen and Bennett<sup>114</sup> reported 6 unsuccessfully treated patients A review of the literature<sup>115</sup> revealed that among 200 cases due to *Streptococcus viridans* and nonhemolytic streptococcus, 6 per cent of the patients recovered after administration of sulfonamides Of 43 patients treated with heparin and chemotherapy, there was 12 per cent recovery Among 24 patients treated by chemotherapy and artificial fever, 4 recovered Of 21 patients treated by chemotherapy and typhoid paratyphoid vaccine, 5 recovered, an incidence of 25 per cent These results are encouraging, but not conclusive, because of the small number of cases and short follow up periods in some

#### PHYSIOLOGY AND BIOPHYSICS

Numerous reports have appeared of research on the physiologic effects of heat, light, electricity and other physical agents Bisgard and Nye<sup>116</sup> found that gastrointestinal motor activity, as indicated by kymographic recordings, was inhibited by the application of heat to the abdominal wall and by ice water taken by mouth Stimulation resulted from application of ice externally and from ingestion of hot water by mouth Another study on the effects of hot and cold applications revealed that the nasopharyngeal irrigations at temperatures above 41°F and below 113°F caused no marked variation in cervical lymph flow At temperatures of 41°F or below and at 113°F or above, the lymph flow increased during the ap

plication or for longer periods if the capillaries were damaged<sup>117</sup> Gammon and Starr<sup>118</sup> investigated the relief of pain by counterirritants and found that the intermittent application of heat and cold was much more beneficial than the use of either agent alone Changes in circulation did not explain the relief of pain, in animal experiments, action potentials from sensory nerves were altered, suggesting a neural mechanism

The cardiovascular effects of heat have been reviewed by Bazett,<sup>119</sup> and the present knowledge of the effect of heat, massage and exercise on lymphatic circulation has been authoritatively discussed by Drinker<sup>121</sup> Diathermy has been shown to have no thermic effects on blood pressure<sup>122</sup> or intestinal activity<sup>123</sup> in animal experiments It was useful in raising the cutaneous temperature of feet reflexly by application to the trunk<sup>124</sup>

In studying reactive hyperemia, Abramson and Ferris<sup>125</sup> found that local heat to the hand was a more potent stimulus than tissue anoxia from ten minute circulatory occlusion, whereas the reverse was true in the forearm and leg Five minute circulatory arrest resulted in relatively complete vasodilatation, according to Eichna and Wilkins,<sup>126</sup> and the reactive hyperemia was only slightly increased by local heat at 104°F or prolonged ischemia (ten to fifteen minutes)

Iontophoresis may cause small but slowly healing burns in spite of the usual precautions Moltor and Fernandez<sup>127</sup> made a careful experimental study of the problem and recommended definite current values for electrodes of various sizes They have expressed this relation of safe current to electrode size in the form of a graph, which should be of value in improving technique and in preventing burns

Other studies on technique and dosage have been reported in relation to short wave diathermy These should be of interest to technicians and have been abstracted in detail by Kovács.<sup>128</sup>

## CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

ANTE-MORTEM AND POST-MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

### CASE 27401

#### PRESENTATION OF CASE

A forty-seven-year-old Greek laborer was admitted to the hospital because of a recurrent pain in the chest, accompanied by shortness of breath and general poor health of nine days' duration.

He had been followed in the Out Patient Department for ten years because of recurring attacks of pain, which radiated over the entire anterior part of the chest, the scapular area and both arms. Since the blood Hinton and Wassermann reactions were strongly positive, antisiphilic therapy was given on several occasions. In all, about two hundred injections of either arsenic or bismuth (mainly the latter) had been given, followed by Mapharsen in small doses. Eight months before admission, the blood Hinton reaction remained positive, although the Wassermann reaction was negative. From the time that the patient was first studied, his heart and great vessels had been enlarged, and he had had an auricular flutter with variable block, usually approaching 4:1. A to-and-fro murmur was always present, loudest in the third left intercostal space. The blood pressure ranged around 140 systolic, 70 diastolic, until the last year, when the diastolic pressure failed, with resultant increase in pulse pressure.

At first, x-ray examination showed dilatation and increased pulsation of the aorta, accompanied by considerable dilatation and pulsation of the pulmonary conus and the hilar shadows. Subsequent roentgenograms demonstrated interesting changes in that the shadow of the heart margin became markedly irregular just above the apex, while the pulmonary conus and ascending aorta appeared to be involved in a double mass. The pulsations of this mass were less vigorous than those of the apex of the heart. The trachea was displaced to the right, and the left main bronchus was unusually small and irregular. On still another roentgenologic examination it was thought that definite, multiple, pulsating saccular dilations extended both anteriorly and posteriorly from the root of the aorta. There was an apparent slight erosion of the left fourth rib near the costochondral junction.

Until entry into the hospital, the patient had remained free from pulmonary congestion, club-

bing of the fingers, ankle edema and cough. He continued at heavy labor with pick and shovel until the last two weeks before entry, although he was cautioned repeatedly against doing so. Two years before the time of his final episode of illness, he had been digitalized, and had continued on this drug intermittently.

Nine days before hospitalization, there was a vague onset of ill health. A day or so later, the old chest pain returned. The patient had been free of this for a long time previously. Simultaneously, he began to experience shortness of breath, and difficulty in getting his breath. On the fourth day before entry, he began to redigitalize himself (having been without digitalis for at least two weeks). The following day he took to his bed. Because of exacerbation of the chest pain, his physician prescribed morphine and nitroglycerin, but neither drug afforded relief.

The past history was significant in that the patient had been a marathon runner while in his twenties. There was a definite history of a penile sore. His family history was irrelevant.

On physical examination, the patient was found sitting upright in bed in some respiratory distress but free from cyanosis. The heart was markedly enlarged, with an increase in the supracardiac dullness. A slight systolic thrill was felt over the third left interspace with a corresponding loud systolic murmur and softer diastolic murmur best heard in this area. There were marked pulsations in the veins of the neck. A loud friction rub was present over the left anterior chest above the heart, together with many coarse, crackling rales, which extended along the sternal border. Some dullness, without rales, was manifested at each pulmonary base. The blood pressure was 140 systolic, 40 diastolic. The pulse was of Corrigan type, with a rate of 84. The rhythm was totally regular at times, and irregular at others. The liver and spleen were not enlarged, and there was no peripheral edema.

The rectal temperature was 102°F., and the respirations 36.

Examination of the blood showed a white-cell count of 13,900 with 90 per cent polymorphonuclears, and a red-cell count of 5,150,000 with 90 per cent hemoglobin. The blood Wassermann and Hinton reactions were positive.

An electrocardiogram showed depression of the ST takeoffs in Leads 1 and 4, and their elevation in Lead 3. The ST segment sagged in all leads, and T was deeply inverted in the first three leads. No axis deviation was present.

An x-ray film showed the heart shadow to have enlarged about 2 cm. since examination in the clinic a month previously. The shadow in the

area of the great vessels was also larger. The left lower lobe of the lung appeared collapsed, with increased aeration of the left upper lobe.

During the night, the patient rested fairly well, although the pain in his chest was only partly relieved by sedatives. The respiratory rate slowed.

The following afternoon, he was found in coma, from which he could not be roused. He was cyanotic, breathing deeply and irregularly about four times per minute. The heart sounds were faint, at 20 per minute. Neither pulse nor blood pressure could be obtained. The patient was given adrenalin and coramine, and rallied slightly. He became restless, and complained of pain in his abdomen. Administration of oxygen improved his color, but both heart and lungs failed within fifteen minutes.

#### DIFFERENTIAL DIAGNOSIS

DR. HOWARD B. SPRAGUE: It seems as if the fundamental situation here must be related to a syphilitic infection. The patient had received a good deal of antisymphilitic therapy. On the other hand, his cardiovascular examination was apparently abnormal by the time he started this treatment. The diagnosis of the anatomic changes appears to rest largely on the x-ray examination. It is true that all this time there was a to-and-fro murmur, loudest in the third intercostal space, which may have been due to true syphilitic involvement of the aortic valve, with aortic regurgitation. One must accept this description, although the murmurs were somewhat more obvious to the left of the sternum. It is fair to say that this does represent aortic regurgitation because we have the statement that he had a Corrigan pulse, although his diastolic pressure was maintained at 70 until the last year before entry, when it finally dropped and the pulse pressure increased. It sounds, then, as if there had not been a high degree of aortic regurgitation. The main pathologic lesion lay beyond the aortic valve.

I should like to have Dr. Schatzki tell me about this x-ray examination, because at one time we are told that the shadow of the heart's margin became markedly irregular, and later on it was thought that definite, multiple, pulsating sacular dilatations were present. I wonder if these sacular dilatations of the aorta made the margin of the heart shadow irregular.

DR. RICHARD SCHATZKI: When one reads the story and hears about the aortic signs and about syphilis, everything seems to be simple. Aortic aneurysm is the first diagnosis. The films, however, are disturbing because they look different from those seen in the usual aortic aneurysms. The lesion is fairly well described in these re-

ports. The striking thing is that this mass lies anteriorly, which means, if it is connected with the aorta, that it comes from the ascending aorta. Usually, if there is an aneurysm of the ascending aorta, it is on the right side of the heart in the anteroposterior films. The abnormality in the anteroposterior film in this case is almost exclusively on the left side. What lies in this area on the left side anteriorly? If it has anything to do with the vascular system, there are two possibilities. One is the pulmonary artery, and the other is the aorta, which is quite close to the pulmonary artery. Which of the two is it? Films taken later show that this mass had grown, but it remained in the same position anteriorly.

DR. PAUL D. WHITE: What is the interval between those two films?

DR. SCHATZKI: Two years. This is a film that was taken on the last day. It is important because it shows the mass and, within the shadow of the mass, a structure that has the appearance of the left hilus or pulmonary artery before it enters the hilus. It would be unusual for the pulmonary artery to be visible if the mass arose from the pulmonary artery.

DR. SPRAGUE: You do not say that this is the pulmonary artery.

DR. SCHATZKI: Not necessarily; but I think it is. I can speak freely because I do not know this case. I am in the same predicament as you. I think what we see within the shadow of the mass is the pulmonary artery or pulmonary conus. The fact that it projects out so far does not necessarily mean that it was enlarged. It may have been pushed over. These films were apparently taken after the last episode. They are not comparable with the first films, because they are taken in a horizontal position. The heart shadow has markedly increased in size, and the mass has still further increased in size even considering the magnification; the aortic shadow seems a little larger. This man had an enlarged heart in the region of the left ventricle and a mass apparently connected with the large vessels, which, so far as its position is concerned, could have arisen from the pulmonary artery, but from these films alone I think it is more likely that it arose from the left border of the ascending aorta.

DR. SPRAGUE: Dr. Schatzki and I agree, anyway. I am not going to be led off the trail by the fascination of syphilitic involvement of the pulmonary artery. We know that when we have thought that sort of thing was present we have been fooled. We are, I think, on safer ground if we say that this was an unusual aneurysm, which arose just above the aortic valve, with a certain amount of dilatation of the root of the

aorta and with some aortic regurgitation, and that the systolic murmur was probably produced in this aneurysmal sac. It undoubtedly displaced the pulmonary artery, and it produced a constriction of a bronchus, resulting in collapse of the left lower lung, but I do not see enough in the picture pointing to trouble in the pulmonary circuit to make me consider this an aneurysm of the pulmonary artery, or perforation from the aorta into the pulmonary artery. There was a growth of this aneurysmal sac, with pain from actual erosion of the chest wall.

Let us discuss a few points in detail. It is unusual for a patient with a syphilitic heart to have auricular flutter. Of the patients autopsied here who have been studied electrocardiographically, I can recall only one with auricular fibrillation. One notes that there were marked pulsations in the veins of the neck, which I assume must have been caused by tricuspid regurgitation. There is no note that these resembled rapid flutter waves. The electrocardiogram shows inversion of the T waves in all three leads, with a depression of the ST takeoffs in Leads 1 and 4 and an elevation in Lead 3, all of which are suggestive, I should think, of some left ventricular strain, even though there is no increase in QRS with a downward direction in Lead 3, which is characteristic of left-axis deviation. That is not too unusual in syphilitic aortitis. About half the patients who have syphilitic aortitis with aortic regurgitation have normal electrical axes, as judged from the direction of QRS. There have been occasional cases of bundle-branch block, both right and left, and an occasional case of right-axis deviation, but in that event there has always been a complication. In this particular case, there might be, I suppose, the added strain on the right side of the heart, if there were an aortic aneurysmal sac distorting or compressing the pulmonary artery, which might lead to some balancing effect in the electrocardiogram.

The final episode is probably explained by the story of what appears to be an enlarging aneurysmal sac, with pain, friction rub and some leukocytosis. It is fair to say that the cause of death was a rupture of the aneurysm. If the aneurysm ruptured into any place where free bleeding could result, whether into a pleural cavity or into the esophagus, trachea or bronchus, I think that the patient would have died sooner than he did. A final x-ray report mentions a marked increase in the heart shadow, and there is a note that the heart sounds were faint, with marked bradycardia. Neither pulse nor blood pressure could be obtained. There is the syndrome of cardiac tam-

ponade. The position of the aneurysm suggests that it ruptured into the pericardium. I am going to assume that that is what happened. In view of the position of this sac at the very base of the aorta, one could guess that there would be some obstruction in the region of one or the other coronary ostia. It does not quite seem as if he had an acute coronary closure as the final episode, although I imagine that that might be possible, or that perforation might in some way have resulted in further compression of the coronary artery. I therefore believe that this was a syphilitic aortitis, with aneurysm of the first portion, presenting to the left and anteriorly, and with final rupture into the pericardium.

DR. WHITE: Just to corroborate Dr. Sprague's opinion about the rarity of pulmonary-artery syphilis and pulmonary aneurysm, I want to say that the most important case that we followed for some years, believing that this was the diagnosis, proved at autopsy to have an aortic aneurysm presenting in the region of the pulmonary artery. That is also true of several other cases on record. Thus, our experience with pulmonary-artery aneurysm has thus far always been disappointing. There is, I think, some suggestion, as Dr. Sprague mentioned, that the pulmonary artery or its branches were compressed by an aortic aneurysm, thereby increasing the size of the main trunk and major branches of the pulmonary artery, along with a shift in position to the left. An increased pulmonary-artery pressure might have overburdened the right ventricle, accounting for the increased pulsation of the neck veins. Another explanation of increased fullness of the neck veins would be mediastinal compression by the aneurysm; that is not so likely, however, because there would then have been engorgement, with little or no venous pulsation. Rupture of the aorta into the pulmonary artery would have produced a continuous murmur, which was not present in this case, and rupture into the superior vena cava would have caused a marked increase in pulsations in the neck veins and also a continuous murmur, which was not present. One case of rupture of the aorta into the pulmonary artery, which was correctly diagnosed before death, had a continuous murmur that made the diagnosis possible. Also, rupture of the aorta into the superior vena cava would have been attended by overwhelming symptoms and a much shorter life than this patient had after the episode. I agree that death in this case was probably due to cardiac tamponade. Hemorrhage into the pericardium is often rather slow and allows a good many hours before death occurs.

## CLINICAL DIAGNOSES

Pulmonary embolism.  
 Syphilis  
 Syphilitic aortitis.  
 Aortic aneurysm?  
 Aneurysm of pulmonary artery?  
 Dissecting aneurysm?

## DR. SPRAGUE'S DIAGNOSES

Syphilitic aortitis, with aortic regurgitation  
 Aneurysm of ascending aorta, with final rupture  
 into the pericardium.

## ANATOMICAL DIAGNOSES

Syphilitic aneurysm of the aorta, with rupture  
 into the pericardium and pulmonary artery  
 Hemopericardium.  
 Syphilitic aortitis.  
 Pulmonary atelectasis  
 Hydrothorax, left.

## PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: This man did have a syphilitic aneurysm of the ascending aorta, which presented anteriorly, as suggested by Dr Sprague and Dr Schatzki. At the time of autopsy it measured 10 by 7 by 4 cm, quite a sizable aneurysm, filled, as usual, with a laminated thrombus. It covered most of the left auricle and presented more anteriorly than any we had seen before. It had ruptured from its posterior aspect into the pericardial sac just below the reflection of the pericardium, and there was 1000 cc of fresh blood in the cavity. The aneurysm was apparently adherent to the pulmonary artery before rupture, because it also ruptured terminally into the pulmonary artery. The left lower lobe and lower portion of the upper lobe were collapsed, apparently because of pressure on the bronchus by the aneurysm, and there was 1000 cc. of straw-colored fluid in the left pleural cavity. The syphilitic aortitis apparently had not extended down to the aortic valve itself, since there was no separation of the cusps at their commissures, and nothing that would indicate that the patient had aortic regurgitation. The coronary mouths were not constricted. The mouth of the aneurysm was located 1.5 cm above the valve, and the tear into the pulmonary artery had occurred 35 cm above the pulmonary valve. The heart was not much enlarged.

DR. SPRAGUE: Was there no obvious increase in the size of the right ventricle?

DR. CASTLEMAN: No; the right wall measured 3 mm.

DR. WHITE: That leaves open the explanation of the diastolic murmur. I suppose it is possible that during life the aortic ring was dilated, allowing some regurgitation that was not apparent when the aorta collapsed after death. The aneurysm was very low in position, was it not?

DR. CASTLEMAN: Yes.

DR. WHITE: It has been my conviction for some time, but this is not generally recognized so far as I know, that in a good many patients with syphilitic aortitis the aortic regurgitation is due, not to a structural change in the valve, but to a dilatation of the very first part of the aorta, involving also the aortic ring. This is much more evident during life than at autopsy.

DR. SPRAGUE: That is borne out by the autopsies here. I have been going over them. There has frequently been no involvement of the valve, even though the medical records continuously report signs of aortic regurgitation.

## CASE 27402

## PRESENTATION OF CASE

A sixteen-year old American schoolgirl entered the hospital complaining of a skin eruption.

Four months before entry, the patient noted on each cheek a patch of redness that was associated with burning. The lesions spread until they crossed the bridge of the nose and assumed a butterflylike outline. Three months later, the redness had spread to her forehead. Two weeks before entry, while taking a bath, she noticed that there were red spots on her feet, and on further examination some were found on her back. Four days before admission, she developed a temperature of 101°F, and a few days later noted red patches in her mouth. Her weight had dropped from 150 to 132 pounds. Otherwise, she had been quite well, except for some loss of energy.

The father, mother and two siblings were living and well. There was no history of tuberculosis.

The patient had eczema as a baby and the other usual childhood diseases, including measles, pertussis, scarlet fever, diphtheria, chicken pox and mumps. She had spontaneous nosebleeds about once a month. There was no history of chest pain, night sweats or cough.

Physical examination showed a well nourished, cheerful girl not acutely ill. The face revealed a masklike involvement, which excepted the mouth, eyes and hair margin. The lesion was described as a dusky erythema of a peculiar purplish hue, yellowish red at the outer margins. It was dry throughout, with a tendency to a fine, grayish scaling. The ears were involved, but the scalp

was free. There were hemorrhagic crusts in the nose. The buccal mucous membrane was denuded in several areas, and the hard palate ulcerated. The lesions were all rather sharply limited. The face was slightly tender and warm. There were a few reddened areas on the back and over the sternum. The tips of the fingers were reddened and slightly swollen. The cervical and left inguinal lymph nodes were enlarged and moderately tender. The edge of the spleen was felt on deep inspiration.

The temperature was 99°F., the pulse 90, and the respirations 20.

Examination of the urine was negative. The blood showed a red-cell count of 4,180,000 with a hemoglobin of 85 per cent and a white-cell count of 5800 with 56 per cent polymorphonuclears. The blood Hinton reaction was negative. The bleeding time was 2 minutes, the clotting time 2 minutes.

During the first week, the patient improved. The white-cell count, which had fallen as low as 2600, rose to 4000. The edema of her face was less marked, and the erythema of the lesions had subsided. About one month after admission, she had a slight fall in her white-cell count that was consistent with new lesions and swelling of the face. She was given nucleotide therapy for about two weeks, without any improvement. She developed generalized choreiform movements, particularly involving the left side, which persisted until death. She had weakness of the left hand, with circular movements. The knee jerks were active. She received x-ray treatment for her skin lesions, with remarkable improvement. After the development of choreiform movements, it was learned that the patient had been treated by a physician one year before entry for nervousness because "she could not sit still a minute." She developed a soft systolic murmur, which was believed to be hemic in character, probably owing to her secondary anemia. The temperature ranged from 99 to 102°F., and shortly after the third month of her stay it rose to 104°F. and she complained of headache, without any local signs or symptoms. Then the temperature rose to 105°F., and she became quite prostrated and dull and complained of a "funny feeling" in her head. The skin was hot and moist, and the skin lesions became redder. She developed pain in the right ear, and examination showed slight edema along one edge of the drum. A pericardial friction rub was heard for the first time. She rapidly failed, became semistuporous, and died three and a half months after admission — seven and a half months after the onset of her illness.

#### DIFFERENTIAL DIAGNOSIS

DR. WALLACE ZELLER: The presence of acute disseminated lupus erythematosus is occasionally unsuspected because of the absence of the skin lesions so frequently found in this disease. In the case under discussion, no such oversight could occur. The skin lesions as described were quite consistent with this diagnosis, and numerous other features presented by this patient were also compatible. The patient belonged to the age group and sex most commonly affected by this disease, and the fever, weight loss, mucous-membrane lesions, lymph-node enlargement, redness and swelling of the fingertips, edema of the face and enlargement of the spleen are all characteristic findings in this widespread constitutional malady. We do not know definitely how long this patient had been troubled with spontaneous nosebleeds, so that their significance cannot be accurately weighed. Since purpura or other hemorrhages were not noted during the course before death, one is not justified in assuming that the nosebleeds were due to thrombocytopenic purpura, which is sometimes associated with systemic lupus erythematosus. The leukopenia, which was consistently found, is, of course, quite characteristic. The soft systolic murmur was thought to be of hemic origin. The degree of anemia at the time this murmur appeared is not stated. Such murmurs, however, may be caused by the endocarditis that sometimes accompanies acute disseminated lupus erythematosus. Their presence in other patients has, in fact, often led to an erroneous diagnosis of rheumatic fever. The terminal occurrence of pericarditis in this patient is the only evidence of involvement of the serous membranes. Headache such as she complained of has been noted in systemic lupus erythematosus, usually without any other evidence of involvement of the nervous system. It is possible that otitis media developed a short time before death. It might have been associated with a hemolytic streptococcus infection, which is often a terminal event in these patients.

There is much in this case history, therefore, to support a diagnosis of acute disseminated lupus erythematosus. Three items deserve special comment, however, since I believe they are unusual in this disease: First, the urine was described as normal, and it is implied that the patient had at no time demonstrated urinary abnormalities. Clinical evidence of renal disease is almost a constant feature of acute disseminated lupus erythematosus. Although it has occasionally been shown that kidney involvement may occur without clinical manifestations in this disease, evidence of its absence here must be weighed seriously in con-

sidering the diagnosis. Secondly, the presence of choreiform movements is, so far as I know, unusual in acute disseminated lupus erythematosus. Convulsions do appear in some cases shortly before death, but I know of none in which chorea has been described. The type and degree of involvement of the nervous system in disseminated lupus is not well known anatomically. Since the disease does involve the nervous system, however, and since widespread damage to small vessels is commonly found, it is not improbable that choreiform movements might occur. They would admittedly be very unusual. Thirdly, it is stated that improvement in the skin lesions followed x-ray therapy. Exacerbations of systemic lupus erythematosus following exposure to ultraviolet rays are well known. Similar exacerbations following roentgen-ray treatment have also been observed. It would be very unusual for exposure to x-rays to be followed by remission rather than exacerbation of the rash. It is not improbable that roentgen therapy was given to this patient on the chance that she might have mycosis fungoides. The fact that her skin improved temporarily following treatment is in favor of such a diagnosis rather than systemic lupus erythematosus. It should be noted, however, that x-ray treatment was not continued and was not tried again when the patient had the terminal exacerbation with further skin involvement. Apparently, the former benefits of the x-ray treatment were not considered to be very striking, or some contraindication to its use was thought to be present.

It is evident, then, that these three unusual features are of only relative importance in diverting us from a diagnosis of systemic lupus erythematosus. The disease can occur without clinical evidence of renal involvement.

Are there other diseases that should be considered in the differential diagnosis? Certainly, Sydenham's chorea in association with rheumatic fever and carditis should be thought of, although the skin and mucous-membrane manifestations would be difficult to interpret on this basis. Since they played so large a part in the clinical picture, I believe this diagnosis is entirely inadequate. The same reasoning can be applied to a consideration of subacute bacterial endocarditis. Since no comment is made regarding blood cultures, I assume that they were negative.

The possibility of dermatomyositis should be considered whenever a diagnosis of systemic lupus erythematosus is under judgment. As Keil<sup>1</sup> has shown, these two diseases may be almost identical clinically. Difficulties in distinguishing between them are usually encountered in patients with

induration of the subcutaneous tissues and muscles, however, and this has not been described in the patient under discussion. The absence of abnormalities of the urine would by itself tend to favor a diagnosis of dermatomyositis as opposed to disseminated lupus erythematosus. Evidence in favor of acute disseminated lupus erythematosus rather than dermatomyositis is more imposing and includes the following: absence of involvement of the eyelids; the occurrence of pericarditis; the apparent absence of any real myositis; the definite enlargement of the lymph nodes; and the occurrence of symptoms referable to the nervous system.

It appears therefore that the probable diagnosis in this case is systemic lupus erythematosus. Since the post-mortem findings in patients dying of this disease are often very few, it is worth while to enumerate those which may be found in this case. The skin lesions, the large lymph nodes and spleen, the pericarditis, possibly with effusion, and the vascular lesions of the central nervous system may well be described. It will be interesting to find if there is gross or microscopic evidence of renal disease, since no urinary abnormalities were noted during life. Endocarditis may or may not have been present. It is quite likely that otitis media was found at death, and there may have been bacterial evidence of terminal septicemia. As has been pointed out in previous conferences here, the final diagnosis must be made by considering the post-mortem findings along with the symptoms and signs present before death.

#### CLINICAL DIAGNOSIS

Acute lupus erythematosus disseminatus.

#### DR. ZELLER'S DIAGNOSES

Acute lupus erythematosus disseminatus.  
Otitis media.  
Terminal septicemia?

#### ANATOMICAL DIAGNOSES

Lupus erythematosus disseminatus, acute.  
Acute endocarditis, terminal (bacterial?).  
Focal necrosis of myocardium.  
Infarcts of spleen, kidneys and brain.  
Otitis media, right.  
Mastoiditis, acute suppurative, right.  
Meningitis, acute.  
Bronchopneumonia, early.  
Pulmonary atelectasis.  
(Chorea.)  
Peritonitis, chemical, from perforation of stomach (probably post mortem).

## PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: As Dr. Zeller has pointed out, the anatomic findings in cases of acute disseminated lupus are often disappointingly few and are at best extremely inconclusive. On the other hand, when the clinical and the anatomic findings are added together, a symptom complex can be built up that is reasonably characteristic. I know of no anatomic finding that is conclusive. Even the skin rash may be very transitory, and no trace of it may be found at the time of death. In this case, it was still present in marked form; otherwise we should have been quite at a loss to make an anatomic diagnosis. A relatively frequent finding in these patients is a polyserositis, but in this case there was no inflammation of the pericardium or pleura and a localized patch of fibrin about the tip of the appendix was all that suggested peritoneal involvement. Enlargement of the spleen and lymph nodes, which is relatively constant, was found in this case. On histologic examination, acute necrosis of the germinal centers was apparent, a very characteristic point in the more acute cases. The heart was normal in size but did show an acute endocarditis of the mitral and aortic valves. From this source, emboli had developed and had produced small infarcts in the spleen and kidneys. The kidneys, furthermore, showed what is called focal glomerular nephritis. By this term we mean findings in occasional glomerular tufts or even in sin-

gle loops of the tufts essentially like those of glomerular nephritis but with many entirely normal glomeruli. This is a frequent finding in disseminated lupus but is also characteristic of subacute bacterial endocarditis, so that in this case it does not serve as a differential point. There was, as was suspected, an acute otitis media and also a mastoiditis on the right. The cerebral symptoms were explained by the presence of a nasal meningitis and also of an early abscess in the right cerebellar lobe. No path of spread of the infection from the mastoid could be made out, so that we do not know whether the cerebellar abscess was secondary to the mastoid or was the result of a septic embolus. Unfortunately no cultures were made of either the endocardial vegetation or of the cerebellar abscess. The character of the endocardial lesion, however, leaves little doubt that the endocarditis was of the bacterial rather than the peculiar nonbacterial type often referred to as Libman-Sacks<sup>2</sup> endocarditis. In summary, it seems probable that we have been dealing with a case of acute disseminated lupus complicated, as these cases not infrequently are, by terminal sepsis, which in this case took the form of a subacute bacterial endocarditis.

were racially or culturally adapted to their patient clientele, but very few were confronted with a failing supply of interns. The primary concern of most hospitals was to secure and maintain the approval of their institutions as suitable places for young graduates to serve internships. They assumed, or perhaps were led to believe, that such approval would vouchsafe for them a continuing supply of interns. Ten years ago, it did.

Today, the problem has changed. Hospitals in general are less concerned with the qualifications of their interns, although they naturally want the best available, and many of them are even worried by the possibility of being unable to provide a fully staffed intern service. Refugees who cannot speak the English language fluently are in demand, and are actually securing histories from patients who cannot understand their questions. Today, there are in the United States one thousand internships for which there are no interns, and for which there are not likely to be interns for many years to come. The military exigencies facing the Nation are beginning to accentuate this situation, but one should not make the mistake of assuming that they have in any way brought this about: the cause is very plain and should be understood by all who are affected by or interested in the problem.

The annual number of medical-school graduates has changed very little during the past ten years; although there was a 20 per cent increase from 1930 to 1937, the number has again fallen off, so that the 1940 and 1941 figures are approximately identical with the average for the decade. Against this relatively fixed supply, there has been a steadily increasing demand for interns' services by the hospitals. Not only has the number of hospitals seeking to use and to train interns increased, but almost all that had had an intern staff have enlarged it. Hospitals have also increased the number of resident physicians in their employ, and in some institutions it has become a part of the hospital economy to give board and room to third-year and fourth-year medical students in return for their services during the evenings and week ends. Apparently, this list

## INTERN SUPPLY AND DEMAND

Hospital administrators expect to face continual new adjustments as the role of the hospital in medical care and medical education continues to change. The medical and surgical service rendered in the modern hospital has come to depend more and more on the activities of interns—usually, recent medical school graduates who seek to gain practical experience and instruction to supplement their medical education. It gradually evolved that the hospitals and the interns each had a need for the facilities and services of the other, and ten years ago, there appeared to be an approximate balance between these mutual facilities and services in the United States. Some hospitals were then at pains to secure interns who

type of hospital service is the least regulated, and can be utilized by hospitals that do not even apply for approval by the Council on Medical Education and Hospitals of the American Medical Association. This dislocation between supply and demand has been made even more stringent by the steady increase in the amount of laboratory work called for today, as compared with that requested ten years ago. Even when this is accompanied by a corresponding increase in laboratory personnel, the work of the interns is not simplified. Consequently, the hospitals of the United States are now engaged in a new type of competition—a competition for their rightful share of the limited supply of available interns.

Among the hospitals in certain metropolitan areas, regulatory procedures have been in operation for many years. So far as they concerned those areas and so far as they did not involve the fourth-year medical students in too many schools, these regulations worked well; but when one metropolitan area advanced the date of its examinations and stipulated that the students selected must immediately accept the appointments or refuse them forthwith, the next year another area was sure to advance the date again. Last year, it was generally agreed that appointments would not be made before a certain day in November, but many hospitals jumped the date when it seemed to be advantageous for them to do so. This year, at least one hospital has written to some of the medical schools asking for the names and addresses of all students in the upper third of the graduating classes—offering to pay the schools for the compilation of such a list—so that they might circularize these men and perhaps inveigle them in advance of other opportunities or commitments. The competition is becoming keen, and for the fourth-year medical student to be competed for rather than to be in competition is a refreshing situation. He who is being competed for, however, must be wary. He should develop sales-resistance, for he will inevitably be approached, proselyted and attracted by whatever devices hospitals can legitimately employ to secure their share of intern attention and service,

and the institutions that talk the loudest should bear particular scrutiny.

Even if the medical schools could increase their output and thus satisfy the demands for intern service,—which at the present time they cannot do without lowering the standards of medical education,—this merely means that a serious oversupply of practicing physicians would eventually occur, since the very increases in the utilization of hospitals that have brought about the present disproportions have already diminished the practice of domiciliary medicine. Economic laws seem to point toward an arrangement whereby those hospitals that do not or cannot provide bona fide educational privileges to their interns would hire graduate interns as resident physicians, thus adding to the cost of medical care but, on the other hand, staking the fledgling physician to the price of an automobile and his first month's rent or the wherewithal with which to pay his debts when he eventually begins private practice.

---

### JOURNAL OF CLINICAL ENDOCRINOLOGY

THE growing field of endocrinology has demanded another journal. In 1917, *Endocrinology* was begun and for many years this important publication, under the direction of the Association for the Study of Internal Secretions, has maintained a high standard of excellence. Papers, however, on the biochemical aspects of the endocrines from highly specialized laboratories have been printed in the same issue with clinical reports. The two aspects of the same problem are, of course, intimately related but may be easily separated without loss to either. Hence, a new journal, the *Journal of Clinical Endocrinology*, published under the same auspices, has been started; it reflects the advances in clinical studies and should prove to be of great use to practicing physicians. The senior publication will continue to report on laboratory investigations and will thus complement the new journal.

The *Journal of Clinical Endocrinology*, begun in January, 1941, with Milton Lee as managing editor and Charles C Thomas as publisher, is a

welcome addition to medical literature. With in editorial committee of distinguished contributors to the field of endocrinology, such as Fuller Albright, J S L Browne, E C Himblen, E L Seyringhaus and K W Thompson, the new journal starts with a sound foundation for a successful career.

## MEDICAL EPONYM

### KLEBS-LOEFFLER BACILLUS

The bacillus of diphtheria was discovered by Edwin Klebs (1834-1913), of Zurich, and reported at the Second Congress for Internal Medicine in Wiesbaden on April 19, 1883. The paper 'Die Diphtherie [On Diphtheria]' is printed in *Verhandlungen des Kongresses für innere Medizin* (2 139-154, 1883). A portion of the translation follows:

In form, these rods are of equal length; they are arranged in a row and on the whole, hardly as large as the bacilli of *A. fur* number are spore bearers, each way having two spores, one at each end.

Friedrich August Johann Loeffler (1852-1915) in a monograph entitled *Untersuchungen über die Bedeutung der Mikroorganismen für die Entstehung der Diphtherie beim Menschen und der Taube und beim Kalbe* [Studies concerning the Significance of Micro organisms in the Etiology of Diphtheria in the Human Being, in the Pigeon and in the Calf], was able to demonstrate by the application of Koch's postulates that the organism described by Klebs was indeed the etiologic factor in diphtheria. In this monograph, which was published in the *Mitteilungen aus dem Kaiserlichen Gesundheitsamte* (2 421-499, 1894), the author refers to previous investigations. A portion of the translation follows:

We thus see that studies dealing with the significance of bacteria that occur in diphtheritic material have not as yet led to any satisfactory conclusions. It seemed imperative, therefore, to attack the solution of this important question with the help of the newest investigative methods, namely Koch's methods of culture on solid media and thus to discover the significance of all these kinds of bacteria. It was necessary, first, to determine which varieties, by reason of their relation to the diseased tissues, seem to be chiefly concerned in the etiology of diphtheria, then to grow these in pure culture, and finally to undertake animal inoculation experiments with the pure cultures in as many species as possible.

There follows a detailed account of the successful investigation that enabled him to say in conclusion: 'We thus have here two examples of perfect, infectious diphtheria of pure bacillary origin.'

## MASSACHUSETTS MEDICAL SOCIETY

### SOCIETY HEADQUARTERS

Owing to the shortage of fuel oil, the Boston Medical Library will be closed on Saturdays, commencing October 4 and continuing until late spring. This will necessitate the closing of the headquarters of the Society and the office of the Journal during the corresponding period. In an emergency, the officers of the Society and the managing editor and associate editors of the Journal will be available through their offices or homes.

### SECTION OF OBSTETRICS AND GYNECOLOGY\*

#### FATAL FIBROCASEOUS TUBERCULOSIS AND FEMORAL THROMBOPHLEBITIS FOLLOWING CESAREAN SECTION

A twenty four year old primipara entered the hospital at term for an elective cesarean section four hours after the rupture of the membranes. The indication for the cesarean section was a small round pelvis.

The heart and lungs were reported to be normal. The patient was first seen when approximately sixteen weeks pregnant and was followed routinely and adequately.

On admission to the hospital, the temperature was 98°F, the pulse 120, and the respirations 20, when the patient returned from the operating room, the temperature was 101°F, the pulse 92, and the respirations 24. From then until the fortieth postoperative day, when she died, the patient ran a continuous fever,—a temperature of 98 to 103°F,—respirations of 30 to 35, and a pulse of 110 to 120. At some time during the puerperium, a right femoral phlebitis developed. A medical consultant saw the patient and noted that there was evidence of a very rapidly developing miliary tuberculosis. The patient was transfused several times and treated conservatively.

Autopsy showed bilateral fibrocaseous tuberculosis, with extensive cavity formation, and right femoral thrombophlebitis.

**Comment.** It is very hard to understand how such an extensive tuberculous process could have existed during pregnancy without being discovered. The operation was performed solely because of pelvic disproportion, and it was not until the temperature rise called attention to the lungs

\*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters could be addressed to Dr. Ray and S. T. us Secretary, 350 Dartmouth Street, Boston.

that the pulmonary process was recognized. It is perfectly possible, in fact probable, that an old tuberculous process was lighted up by the infection that followed the cesarean section. Hence, the cesarean section was probably the indirect cause of death. If the infection had not resulted, the tuberculous process would probably have remained not only quiescent but entirely unrecognized.

Tuberculosis is not a common complication of pregnancy. Patients with mild cases under hospital care may go through pregnancy without undue risk, and it is only in advanced cases that fatalities ensue.

#### DEATHS

**CHOLERTON**—HERBERT CHOLERTON, M.D., of West Somerville, died September 25. He was in his sixty-ninth year.

Born in Manchester, England, Dr. Cholerton received his degree from Harvard Medical School in 1901. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, his mother, a sister, and a brother.

**KELLEHER**—PATRICK F. KELLEHER, M.D., of Cambridge, died September 25. He was in his seventy-fourth year.

Dr. Kelleher received his degree from Tufts College Medical School in 1896. He served on the staffs of St. Elizabeth's and Cambridge City hospitals, and was a fellow of the Massachusetts Medical Society and the American Medical Association.

His son and a sister survive him.

**LANE**—EDWARD B. LANE, M.D., of Milton, died September 17. He was in his eighty-second year.

Born in Melrose, he attended Boston University and graduated from Harvard University. He received his degree from Harvard Medical School in 1885 and served his internship at the McLean Hospital, after which he became assistant physician at the Northampton State Hospital. In 1895, he was appointed first superintendent of the Boston State Hospital, a position that he held until 1905, when he retired to private practice.

From 1898 to 1903, Dr. Lane was clinical instructor in mental diseases at the Harvard Medical School, resigning to become professor of mental diseases at the Tufts College Medical School; he retained this position for twenty-five years. He was formerly resident physician at the Adams Nervine in Jamaica Plain. He was a member of the Massachusetts Medical Society, the American Medical Association, the American Urological Association, the American Psychiatric Association and the Dorchester Medical Club.

His widow, three sons and a sister survive him.

**MALLORY**—FRANK B. MALLORY, M.D., of Brookline, died September 27. He was in his seventy-ninth year.

Dr. Mallory received his degree from Harvard Medical School in 1890. He was professor of pathology at the Harvard Medical School for many years and was head of the Pathological Laboratory, —later called the Mallory

Institute of Pathology, —Boston City Hospital, from 1897 until his retirement in 1933. He was a fellow of the Massachusetts Medical Society and the American Medical Association and a member of the American Association of Pathologists and Bacteriologists, having served as its treasurer for many years. Dr. Mallory was the author of two standard pathological textbooks and many original articles, and for fifteen years was editor of the *American Journal of Pathology*.

He is survived by a sister, Miss M. Eleanor Mallory, of Avon Park, Florida, and by two sons, Dr. Tracy B. Mallory and Dr. G. Kenneth Mallory, both of Brookline.

**TOBEY**—GEORGE L. TOBEY, Sr., M.D., of Medonak, Maine, died September 18. He was in his eighty-ninth year.

Dr. Tobey formerly served on the staff of the Clinton Hospital, and had been district medical examiner. He was a former member of the Massachusetts Medical Society, and was a member of the *Maine Medical Association* and the American Medical Association.

His sons, Dr. George L. Tobey, Jr., Dr. Harold G. Tobey, and Guy D. Tobey, survive him.

#### CORRESPONDENCE

##### INFORMATION CONCERNING THE ARMED FORCES IN PHYSICIANS' WAITING ROOMS

*To the Editor:* During the past few weeks, several medical men in New England have informed this headquarters that they would be pleased to take a more active part in the national defense effort. In particular, several physicians have signified their desire to secure accurate information about current opportunities in the United States Army for young men who were their patients or relatives and friends of patients.

In this connection, it has also been suggested that many professional offices would lend themselves most fittingly to the display and possible distribution of reliable information about the armed services in the form of official publications, which might be included with the other standard reading matter of a physician's waiting room.

May I take this opportunity to invite any physician in New England who wishes to join others in this vital phase of national defense to notify the Commanding General, First Corps Area, Army Base, Boston, Attention CARO? Appropriate material will promptly be furnished.

The fine spirit that your profession has already displayed in innumerable ways during the current emergency makes me sure that all its members who find it possible will co-operate in this matter.

F. B. WILBY

*Brigadier General, United States Army*

First Corps Area  
Army Base, Boston

##### PREMARITAL MEDICAL EXAMINATIONS

*To the Editor:* I am much interested in House Bill No. 460 dealing with premarital physical examinations, a transcript of which appeared in the August 28 issue of the *Journal*.

Section 20B states, "If such physician, in making such examination, discovers evidence of any infectious disease declared by the state department of public health to be dangerous to the public health, he shall inform both parties of the nature of such infectious disease and of the pos-

sibilities of transmitting the same to his or her marital partner or to their children. Such examination shall include a standard serological test for syphilis. If either applicant is suffering from one of the more obvious reportable diseases, like smallpox or diphtheria, the physician's problem is relatively simple. But it is quite evident from the demands for a serologic test for syphilis that the intention of the bill is likewise to exclude gonorrheal disease in both applicants.

Shall the physician rest content with a cursory injection of the antenatal phallus, or shall he also make sure the prospective bridegroom's prostate is secure with microscopic evidence of purity of soul and sanctity of habit? And if so, should he be content with aught but cultural evidence of noninfectiousness? And what of the blushing bride? To rest content here with a negative Hinton test and a throat and skin free of obvious infection is hardly to carry out the purpose of this legislation. Are we to certify that the lady is free of infectious disease dangerous to the public health when we have the remotest idea of the existence or character of discharge? And shall we be satisfied with a non-pudendal smear, or must we go into the problem deeply? Here we are faced with a perplexing social taboos and sentimental prejudices.

To imply ridicule of this estimable piece of legislation is farthest from my thoughts, but on the shoulders of every practicing physician has descended a very real responsibility to the State as well as to the patient. How, then, an examination should be performed in order to certify the spirit and the letter of this law and to enable the physician to assert without fear of serious consequence that neither party harbors a reportable contagious disease? Unless frank discussion of this problem prior to some unanimity of opinion and of practice the whole can become a farce that merely creates a sense of insecurity in the minds of the affianced.

ALLEN S. JOHNSON, M.D.

121 Chestnut Street  
Springfield, Massachusetts

## POST PARTUM EMBOLISM

To the Editor: In the August 28 issue of the *Journal* under the Section of Obstetrics and Gynecology of the Massachusetts Medical Society, a case of post partum phlebitis and fatal pulmonary embolism was presented and the assertion was made that death might have been averted had the patient been kept in bed for a longer period. The fever was assumed to have been due to pelvic thrombophlebitis, although no evidence other than fever is given to support this diagnosis. On the other hand, the presence of tenderness in the leg, together with fever, should have been regarded as presumptive evidence of thrombophlebitis of the deep veins in the lower leg.

The assumptions made in that report deserve revision in view of the recent evidence concerning the etiology of pulmonary embolism to wit, that the vast majority of emboli arise from thrombophlebitis of the deep veins of the lower leg; that the treatment of such thrombophlebitis by prolonged rest in bed is not an effective safeguard against the occurrence of embolism; that the existence of an unexplained fever and tenderness in the lower extremity makes it incumbent on the physician to make or dismiss the diagnosis of thrombophlebitis on the basis of x-ray visualization of the deep veins by Bauer's technique, that once the diagnosis is made the only certain prophylaxis against embolism is immediate ligation of the femoral vein proximal to the clot, or heparinization, which is less

desirable for reasons already pointed out by various writers.

In the case referred to it is clear from existing data that keeping the patient in bed for a longer period would not have guaranteed the avoidance of embolism whereas ligation performed in time and in the right circumstances would. Gynecologists and obstetricians should revise their assumption that the site or origin of emboli in their cases is from the pelvic veins. This belief continues to render them helpless to avoid the calamity of embolism. The facts warrant an optimistic view in regard to an effective prophylactic technique against embolism. Careful observation of the lower extremities in post partum and post-operative patients should lead to a sharp reduction in the incidence of fatal pulmonary embolism.

ARNOLD STARR, M.D.

520 Beacon Street  
Boston

## DEFENSE COUNCILS

To the Editor: According to a joint statement issued on September 4 by the director of the Office of Civilian Defense, F. H. LaGuardia, and the chairman of the American National Red Cross, Norman H. Davis, state and local defense councils are the official agencies responsible for the co-ordination of all available resources that may be required for civilian protection in the event of belligerent action. Defense councils should therefore acquaint themselves with the resources of the local Red Cross chapters in providing food, clothing, shelter, nursing care, transportation and other basic necessities and should integrate them into the comprehensive local program. Duplication of trained and experienced personnel and of available supplies of the Red Cross should be avoided except where supplementation is essential to meet the anticipated needs of the community.

GEORGE BAEHR, M.D.  
Chief Medical Officer

Office of Civilian Defense  
Washington, D. C.

## BOOK REVIEWS

*Scabies—Civil and Military Its prevalence prevention and treatment.* By Reuben Friedman, M.D. 8°, cloth, 288 pp. New York: Froben Press, 1941. \$3.00.

The subject of scabies is thoroughly reviewed in this book, particularly in its historical and military aspects. Over two hundred pages are devoted to the importance of scabies in relation to war, but there are also chapters on scabies in Colonial America and similar historical data. The material, in general, is badly presented and the book is difficult to read. Considerable semi-irrelevant or badly digested facts are included. Moreover, the format is unattractive, and in many places there is evidence of lack of care in printing. The book, although it contains some material of interest, is not one that can be enthusiastically recommended.

*Textbook of Medicine.* By various authors. Edited by J. J. Conybeare, M.C., D.M. (Oxon.) F.R.C.P. Fifth edition. 8°, cloth, 1131 pp., with 24 illustrations, and 31 x-ray plates. Baltimore: Williams and Wilkins Company, 1940. \$7.50.

The fifth edition of this book, which was first published in 1929, is an indication of its worth to the medical

profession. Made up of contributions by various authors, but edited by Dr. Conybeare, physician to Guy's Hospital in London, this volume has long maintained an important place in the world of medical textbooks. This edition contains a great deal of new material, for many sections have been partially rewritten and some completely revised. Articles on sulfonamide therapy, blood transfusion, herniation of the nucleus pulposus and similar modern additions to medical knowledge are included. It has not been possible, however, to keep the book strictly up-to-date, largely because of the emergency created by the war in England. The authors are apparently not acquainted with many recent additions to medical literature, although the volume maintains its position as an important textbook.

*Medical Diseases of War.* By Sir Arthur Hurst, D.M. (Oxon.), F.R.C.P., with the co-operation of H. W. Barber, M.D. (Cantab.), F.R.C.P., F. A. Knott, M.D. (Lond.), M.R.C.P., and T. A. Ross, M.D. (Edin.), F.R.C.P. 8°, cloth. 327 pp., with 37 illustrations and 4 plates. Baltimore: Williams and Wilkins Company, 1940. \$5.50.

This book, a new edition of one first published in 1916 and republished in 1918, will be found especially helpful to neurologists and to all interested in the neuroses of war. It is based largely on the author's wide experience in World War I as neurologist to Guy's Hospital, officer commanding Seale-Hayne Hospital for Functional Nervous Disorders and consulting physician to the Salonika Army, but under conditions so far experienced it may not be so applicable in World War II.

When one realizes that almost 6 per cent of the 341,025 discharges of soldiers from the British Army from 1914 to the end of April, 1918, were due to war neuroses, the value of recognizing and treating these cases correctly is evident. Hurst's remarks in Chapter I, "Predisposing Causes of War Neuroses," will repay careful reading. Other chapters are entitled "Hysterical Symptoms in Soldiers," "Hysterical Contractures," "Hysterical Postures and Gaits," "Hysterical Tremors" and "Hysterical Blindness"; they contain numerous brief case records, which are instructive. Many results and cures are almost miraculous.

Of especial interest is Chapter XVI by T. A. Ross, entitled "Anxiety Neuroses of War." Here, in particular, psychotherapy, with explanation to the patient, persuasion and re-education, has worked wonders. The chapter, "Soldier's Heart," is very good; in great measure, this is based on Sir Thomas Lewis's book, published in 1918. The section by H. W. Barber, "Skin Disease in War," is of special value. Medical officers of the rapidly expanding Army of the United States, an army composed of men who are very liable to be infected in crowded barracks, should study this section with care.

The title of this volume is somewhat misleading, since almost half of the book is given over to the neuroses of World War I, and the other half concerns almost entirely a number of medical diseases, such as trench fever, typhoid and paratyphoid fevers, bacillary dysentery, epidemic jaundice and tetanus, all of which promise not to be important in World War II, because conditions are so different from those in 1914-18. One expects to have epidemics and perhaps pestilence, but more probably among the civilian population than among the military forces.

Of great value are the references to the published literature, at the end of each chapter. An index also adds to the general usefulness of the volume. This book can well be recommended to those interested in military medicine.

*Neurology: Lectures for medical students and general practitioners.* By Knud H. Krabbe, M.D. 8°, paper, 387 pp., with 4 illustrations. Copenhagen, Denmark: Einar Munksgaard, 1941. 12 Dan. Cr.

Dr. Krabbe, a well-known neurologist from Copenhagen, has long been a lecturer in the hospital and medical school in that city. He is widely known as a distinguished contributor to the literature on neurology. His lecture notes, slightly expanded and carefully translated, are now published in English, a remarkable contribution from Denmark in a time of great uncertainty, because of the German occupation.

The lectures themselves are effectively compiled, and although they report what must be considered only as routine neurologic information, they are written in a pleasant style, with remarkable completeness of material. The book forms an excellent introduction to the subject and should be widely read in this country by medical students and practitioners. There is a flavor, moreover, of continental neurology, not found in American and English textbooks. One should not look, however, for a complete treatise on the subject. These are introductory lectures, but as such are sound, clear and extremely readable. Seldom has the reviewer met with a book by a foreign author that has pleased him more in its English dress. This volume is highly recommended.

In the May 15, 1941, issue of the *Journal*, the price of this book was incorrectly listed as \$12.00. It should have been Danish crowns, or about \$3.00, which is a reasonable price for an important publication.

*Orbital Tumors: Results following the transcranial attack.* By Walter E. Dandy, LL.D., M.D. 8°, cloth, 168 pp., with 100 illustrations. New York: Oskar Piess, 1941. \$5.00.

Up to comparatively recent times, orbital tumors have been operated on by ophthalmologists, who have used the ordinary orbital approach. With the advent of neurosurgery, it was soon discovered that orbital tumors are often intracranial tumors, with extensions into the orbital space, and thus cannot be entirely removed when operated on through the anterior part of the eye. Nearly 75 per cent of primary orbital tumors are also found in the intracranial chamber. Because of this and also because of the more favorable chance of removing the tumor in the orbital cavity, Dandy advocated the intracranial approach as early as 1921. His point of view has now been widely accepted, and, except for tumors lying in the anterior portion of the right orbit where there is no reason to suspect an intracranial extension, all other tumors of the orbit should be exposed by the neurosurgeon. This, indeed, according to Alan C. Woods, who writes the preface to Dandy's book, has become the routine practice at the Johns Hopkins Hospital. The monograph reports 31 cases, in most of which the tumors were removed by Dandy. The book is finely illustrated, has a good bibliography, and is a splendid example of a small monograph on a single field of neurologic and neurosurgical interest. To neurologists, the book is one of prime importance, and it is hoped that the ophthalmologist, too, will recognize its value.

## NOTICES

### HARVARD MEDICAL SOCIETY

Beginning October 14, the Harvard Medical Society will meet once a month on the second Tuesday of each

month, with the exception of November, at 8 15 p m in the amphitheater of the Peter Bent Brigham Hospital. The program for the October 14 meeting is as follows:

Clinical presentation  
Recent Advances in Experimental Renal Hypertension  
Dr Lewis Dexter

#### JOSEPH H PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston  
Lecture Hall, 9-10 a m

#### MEDICAL CONFERENCE PROGRAM, OCTOBER

Wednesday, October 8—Spleen Facts and fancies Dr William Dameshek.

Friday, October 10—A Routine Office Cardiovascular Physical Examination Dr Samuel A Levine

Wednesday, October 15—A Dental Pediatric Presentation Dr F C McDonald and Dr Leonard Despres

Discussion by Dr Basil G Bibby and Dr Paul Boyk

Friday, October 17—Gastric Ulcer Dr Sara Jordan

Wednesday, October 22—Acne, Hirsutism and Menstrual Disorders Dr C H Lawrence

Friday, October 24—Physical Fitness in Late Maturity Dr Robert T Monroe.

Wednesday, October 29—X ray Demonstration Dr Alice Ettinger

Friday, October 31—The Differential Diagnosis of Hemoglobinuria Dr T Hale Ham

On Tuesday and Thursday mornings, from 9 to 10 o'clock, Dr S J Thannhauser will give a medical clinic on hospital cases

On Saturday mornings, from 9 to 10 o'clock, there will be a presentation, with discussion, of dispensary and district cases

There will be no morning medical conferences the week of November 3, during the meetings of the American College of Surgeons

#### JEWISH MEMORIAL HOSPITAL

The first diagnostic therapeutic conference of the Jewish Memorial Hospital will be held at the hospital 55 Townsend Street, Roxbury, on Thursday, October 9, at 11 a m Dr Reginald Fitz will speak on Heart Disease.

Interested physicians and medical students are cordially invited to attend

#### CONSULTATION CLINICS FOR CRIPPLED CHILDREN

The date of the consultation clinic for crippled children, to be held in Gardner, has been changed from October 10 to October 21. The dates of the other clinics is announced in the September 25 issue of the *Journal* remain unchanged

#### SUFFOLK DISTRICT MEDICAL SOCIETY

During 1941-1942, the Suffolk District Medical Society will hold two meetings, instead of three as in previous years. Both meetings are business meetings. The executive committee may, for business or scientific reasons, announce additional meetings during the coming year

Wednesday, October 22, Boston Medical Library, 8 15 p m "Personal Experiences in Unoccupied France, 1941" Dr Harold C Stuart

Wednesday, April 29 Annual meeting Boston Medical Library 8 15 p m Election of officers Virus Infections of the Central Nervous System Drs Houston Merritt and John H Dingle

#### BOSTON DOCTORS SYMPHONY ORCHESTRA

The Boston Doctors' Symphony Orchestra will resume rehearsals, under Alexander Thiede, on Thursday, October 9, at 8 30 p m at Station WMEN, 70 Brookline Avenue, Boston. Those interested in becoming members should communicate with Dr Julius Loman, 520 Beacon Street, Boston (KEN 3200 or LON 2155)

#### AMERICAN SOCIAL HYGIENE ASSOCIATION

The American Social Hygiene Association is arranging a dinner to mark the thirtieth anniversary of the announcement of the discovery of salvarsan by Dr Paul Ehrlich. Mrs Ehrlich will be the guest of honor on this occasion. Among the other speakers will be Dr Thomas Parran, surgeon general of the United States Public Health Service. The Honorable Frances Payne Bolton will preside.

The dinner will be held in the Jade Room of the Waldorf-Astoria, on Saturday evening, October 11, at 7 30. Tickets may be obtained from the American Social Hygiene Association, 1790 Broadway, New York City, at a cost of \$3.85, including gratuity.

#### SOCIETY MEETINGS AND CONFERENCES

##### CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, OCTOBER 5

MONDAY OCTOBER 6  
10-11 15 p m Clin copathological conference Dr Bent Brigham Hospital amph theater

TUESDAY OCTOBER 7  
10-10 a m Medical clinic Dr S J Thannhauser Joseph H Pratt Diagnostic Hospital  
12 15-1 15 p m Clin coronecological conference Peter Bent Brigham Hospital amph theater

WEDNESDAY OCTOBER 8  
American Academy of Pediatrics Hotel Statler Boston  
9-10 a m Spleen Facts and fancies Dr William Dameshek Joseph H Pratt Diagnostic Hospital  
12 m Clin copathological conference Cl Thannhauser  
2 p m New England Dermatological Society Massachusetts General Hospital Skin Out Patient Department

THURSDAY OCTOBER 9  
9-10 a m Medical clinic Dr S J Thannhauser Joseph H Pratt Diagnostic Hospital  
American Academy of Pediatrics Hotel Statler Boston  
11 a m Heart Disease Dr Reginald Fitz Jewish Memorial Hospital 55 Townsend Street Roxbury

FRIDAY OCTOBER 10  
American Academy of Pediatrics Hotel Statler Boston  
9-10 a m Routine Office Cardiovascular Physical Examination Dr Samuel A Levine Joseph H Pratt Diagnostic Hospital  
8 15 p m The Heart and Treatment of Dr Alice Ettinger  
Dr Edward L Lurie United States Naval Hospital Chelsea

## BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

*The Care of the Aged (Geriatrics).* By Malford W. Thewlis, M.D., attending specialist in general medicine, United States Public Health Hospitals, New York City, attending physician, South County Hospital, Wakefield, Rhode Island, and special consultant, Rhode Island Department of Public Health. Third edition, entirely rewritten. 8°, cloth, 579 pp., with 50 illustrations. St. Louis: The C. V. Mosby Company, 1941. \$6.00.

*Effective Living.* By C. E. Turner, Sc.D., Dr.P.H., professor of biology and public health, Massachusetts Institute of Technology; and Elizabeth McHose, M.A., director of physical education for girls and chairman of the Health Council, Senior High School, Reading, Pennsylvania. 8°, cloth, 432 pp., with 164 illustrations. St. Louis: The C. V. Mosby Company, 1941. \$1.90.

*Clinical and Experimental Investigations on the Genital Functions and Their Hormonal Regulation.* By Bern hard Zondek. 8°, cloth, 264 pp., with 59 illustrations and 44 tables. Baltimore: Williams and Wilkins Company, 1941. \$4.50.

*Studies from The Rockefeller Institute for Medical Research.* Reprints, Vol. 118. 4°, paper, 628 pp., with 141 illustrations, 20 plates, 80 tables and 18 charts. New York: Rockefeller Institute for Medical Research, 1941. \$2.00.

## THE OPEN SAFETY PIN\*

### A Consideration of Its Peroral Removal from the Upper Air and Food Passages

LAMAR G. RICHARDS, MD†

BOSTON

AS APPLIED to a peroral foreign body, there are few greater misnomers than the term "safety pin." So far as its presence in the upper air or food passages is concerned, this type of pin is at once one of the most dangerous and frequent objects to gain accidental access to these regions. The danger arises primarily from the fact that in most cases the pin tends to enter the pharynx or larynx with the point unguarded and held at a wide angle by the spring, thus presenting a hazardous situation in which the delicate walls of the upper air and food passages are subject to pressure and possible perforation by the point of the pin. The frequent occurrence of such accidents is due to the almost universal use of the safety pin in dressing infants—an age group in which this type of foreign body is most frequently seen. In spite of constant medical admonition, mothers and attendants continue to leave safety pins open and with unprotected points within easy reach of babies whose natural instinct is to put them in the mouth. Added to this is the bad example so often set by mothers themselves in holding such pins in the mouth, with the inevitable result that youngsters tend to imitate this indiscretion. Occasional accidental swallowing of the pin by an adult may result from this pernicious habit.

I believe that this situation warrants closer attention from the pediatrician and the general practitioner, who will so frequently be the first to see such patients. For this reason I am presenting some conclusions drawn from personal experience with regard to clinical observations and secondary to the operative technic involved in the peroral removal of these foreign bodies.

In a recent article, Clerf<sup>1</sup> reports that of over 825

foreign bodies removed endoscopically, 77 were safety pins. In 59 cases, or 77 per cent, the pin was removed from the food passages, in the remaining 18 it had lodged in the air passages. In a personal series of over 150 peroral foreign bodies, 25 have been some form of safety or clasp pin, 90 per cent of which were in the food passages.

Because of this experience with the removal of such pins from the upper air and food passages, I have come to believe that no specific operative technic is applicable in all cases. Chief consideration must be given to the location of the pin and the relation of the point to this location. As an aid in the visualization of the commonest sites of pin lodgment, there is reproduced in Figure 1 a group of photodiagrammatic x-ray films to show representative situations within which, with slight variations, will fall almost all open safety and clasp pins that accidentally find their way into the air and food passages. Divergencies from these typical positions will of course occur, but slight differences of a centimeter above or below the midesophageal region or a minor tilting of the pin to the right or left has no essential bearing on satisfactory methods of removal later to be discussed. These representative positions will first be considered individually.

#### LOCATION OF PIN

##### *Hypopharynx*

It is in the hypopharynx (Fig 1A), particularly in infants up to the age of one year, that one finds over 50 per cent of all open safety pins. The point is usually upward either to the right or to the left and most frequently buried, at least at the termination of the shaft, in the mucosa of the lateral pharyngeal wall. In this position, the spring is resting just at the mouth of the esophagus and occupies the somewhat narrow constriction known

\*From the Bro. Joseph Clinic, Massachusetts Eye and Ear Infirmary.  
†From Boston Mass. House of Eye and Ear Infirmary.

as the cricopharyngeal ring formed by muscle fibers that, attached to the posterior surface of the cricoid cartilage, are embedded in the lateral and posterior surfaces of the constrictor muscles. This muscular ring exerts a somewhat sphincterlike action and is recognized as a line of demarcation or boundary with respect to any esophageal foreign body, depending on whether such objects

The relation of the plane of the pin to that of the hypopharynx is of almost pathognomonic significance. Any pin in the hypopharynx will appear, in a true anteroposterior roentgenogram, in its full expanse, with but little if any foreshortening, as shown in Figure 1A. For this reason, in a true lateral view, the pin will be seen from the side and hence will show no evidence of details

FIGURE 1. *Photodiagrams of Open Safety Pins in Representative Positions in the Upper Air and Food Passages.*

A—hypopharynx, point up; B—hypopharynx, point down; C—larynx, point up; D—esophagus, point up; E—esophagus, point down; F—right bronchus, point up. An intentional disproportion between the size of the pin and the roentgenogram has been employed for purposes of illustration.

are above the cricopharyngeus muscle or below it. This differentiation, as will be seen later, is of the greatest importance in selecting the method of removal best suited to the individual case. The keeper of a pin in the hypopharynx is usually found at a slightly higher level than the point, but slight changes in angulation may leave both keeper and point on a horizontal line. Most frequently, the keeper shaft of the pin will be in a vertical position, the pointed shaft assuming an angulation with the vertical dependent on the degree to which the pin is open.

of expansion or relation of point and keeper to each other. Since an absolutely uniform lateral exposure is difficult to secure, there will, in this exposure, frequently be a slight divergence between the two shafts, but this appearance is quite distinct from that seen when the pin is lodged in the larynx (Fig. 1C).

Lodgment of a pin in the hypopharynx depends somewhat on its size. The larger the pin, the greater the spread at the spring and the less likely it is, particularly in young children, to pass deep into the upper esophagus. In spite, however,

of any relatively high roentgenologic appearance, it is only rarely that the pin can be seen on direct inspection of the throat. When this is possible on forceful depression of the tongue, the top of the keeper may be glimpsed, a point of importance only if x-ray facilities are unavailable or yield negative results.

Far less often a pin in the hypopharynx comes to rest point downward (Fig. 1B). This position is at once recognizable roentgenologically, the pin still assuming its typically transverse relation in the anteroposterior view.

### *Larynx*

It is Nature's intention that any appropriate object put in the mouth shall be swallowed, passing into the esophagus and thence into the stomach. To this end, a complicated and beautifully co-ordinated series of muscular movements propels the object along the proper course. For this reason, more than 90 per cent of all open pins that find accidental lodgment in a child's throat are found in some part of the alimentary tract—hypopharynx, esophagus or stomach. During the act of swallowing even so awkward an object as an open safety pin, there takes place a temporary closure of the larynx or gateway to the upper air passages, which prevents any foreign substance from gaining access to this vital and sensitive region. Only occasionally, in an unguarded moment, can a foreign object near the orifice of the larynx, during a deep inspiration provoked by laughing, coughing or crying, evade the swallowing guardian and so be drawn into the upper airway. This situation, which the layman interprets as "swallowing the wrong way," causes such small objects as nut fragments, tacks and other bits of hardware to reach the tracheobronchial tree.

This same explanation accounts for the occasional lodgment of an open safety pin in the larynx (Fig. 1C). Since the diameter of the latter is much less than that of the hypopharynx, it is quite understandable why a pin of any except extremely small size meets obstruction to further advance and therefore, fortunately, fails to enter the trachea. Again, as in the hypopharynx, almost all such open pins in the larynx come to rest with the point upward but with the fundamental and diagnostically significant difference that the pin lies in the sagittal plane. Therefore, a view of its details in the plane of expansion is seen only in lateral roentgenograms of the neck. In an anteroposterior film, there appears usually only a single or closely approximated double shadow, and even this is obscured by the density of the cervical spine directly behind it. The assumption of such a position by an open pin in the larynx is owing to the fact that whereas the greatest width of the

pharynx and esophagus is in the frontal plane, that of the larynx is in the sagittal plane, and only by conforming to this plane can any appreciable part of the pin pass between the vocal cords. It is at once obvious that this fixed relation of the pin to the plane of the food passage or airway is of the utmost diagnostic value in determining the location of the foreign body. More commonly, an open safety pin enters the larynx with the pointed shaft anteriorly, the point itself protruding either just above the cordal junction in the anterior commissure or just beneath this point and hence below the cordal junction. Depending on the size of the pin, the keeper will occupy a position above or between the arytenoid cartilages, in either event resting against the interarytenoid fold in the midline. Only very rarely will such an open pin enter the larynx point downward, when it will still assume the characteristic anteroposterior plane and will be seen in its expanded position only in the lateral film.

### *Esophagus*

It is in their lodgment in the esophagus proper (cervical, upper thoracic or lower thoracic) that open safety pins create the greatest hazard to the patient and the greatest endoscopic problem for the bronchoscopist. Once the pin has passed the sphincter of the cricopharyngeus muscle, it comes to rest in some portion of the esophagus, most commonly in the region illustrated in Figure 1D. Variations somewhat above or below this representative point have no special bearing on the problem of removal and are dependent on such extraesophageal relations as the crossing of the left main bronchus or pressure from the arch of the aorta. So long as such pins do not pass promptly into the stomach, they call for endoscopic removal, and the assumption that they will pass spontaneously is unwarranted by experience. Here again, as in the hypopharynx, the pin will assume its characteristic frontal plane, its detailed relation being clearly evident in anteroposterior roentgenograms.

By far the greatest number of such esophageal pins are found point up. When the reverse is true, there is always a strong suspicion that the pin, advancing spring downward, actually entered the stomach, being subsequently regurgitated back into the esophagus and lodging this time with the point downward (Fig. 1E). Only in cases of extremely small baby safety pins in older children or adults would it normally be possible for an open safety pin to advance to the midesophagus through the constricting cricopharyngeus muscle while maintaining the point in advance.

### *Main Bronchus*

It requires no knowledge of peroral endoscopy to appreciate the hazards to the patient and technical difficulty of removal of an open safety pin lodged in the main bronchus, the rarest of locations, particularly if point up (Fig. 1F). As a rule, only rather small pins can, through sheer impossibility of passing the larynx, reach the lower bronchial tree, barring always the occasional misfortune of dislodgment from the larynx during attempted removal from the latter. The angular spread of any open pin in the bronchus must of necessity be limited, since the bronchial diameter automatically precludes wide angulation.

### *Stomach*

Finally, open safety pins not infrequently are first discovered to be in the stomach, having, through Nature's providence, passed without accident through the esophagus. Whether, once arrived in this temporarily safe harbor, such pins merit endoscopic extraction is a matter of experience, individual judgment and meticulous study of the subsequent clinical course, and constitutes a subject best discussed in connection with the considerations of removal.

### DIAGNOSIS

It is self-evident that the proper treatment of any patient harboring an open safety pin in his air or food passages presupposes a diagnosis of its presence. Consideration must first be given to a history of ingestion or aspiration, or at least of an opportunity for this. In most cases, such a history must come from the parents, almost always the mother or an attendant, less frequently from an older child. Infants or small children can obviously afford no help in such a situation. It is interesting to note that a positive and volunteered story of the swallowing of an open safety pin is much oftener available than that of nuts aspirated into the bronchus, for example. In a personally observed series of 40 cases of such aspirated nuts,<sup>2</sup> the proportion of delayed diagnosis and prolonged sojourn of the foreign bodies before removal was far higher than that of open pins. This fortunate circumstance results, in all probability, from the fact that most persons caring for infants and young children have a fairly accurate idea of the number of pins customarily used in dressing them and of their whereabouts during any moment of changing or undressing. If, during an unguarded moment, the infant procures such a pin, puts it in his mouth and swallows it, it is quite likely that the pin will be missed and a prompt search made for it. With failure to find it, suspicion is very apt to arise that

the child has swallowed it. If, at the same time, there are any such untoward signs or symptoms as coughing, gagging, choking and vomiting, the possibility is likely to be still further considered and a physician called. Apparently, perhaps as the result of greater publicity, parents today seem much more conscious of pins than of such a foreign body as a peanut, with which, as evidenced by the above-mentioned series of 40 cases, the time interval between aspiration and bronchoscopic removal is much longer.

Another factor operating to effect prompt recognition of a safety-pin accident is the age of the patient. In a high percentage of cases, this is less than one year, hence patients have not the freedom to come and go and so, of their own accord, to put other foreign objects in their mouths. In the group aspirating some form of nut, the average age of the patient was over three years, obviously precluding a parental supervision comparable to that of infants under a year of age. Nevertheless, there have been patients who have swallowed or aspirated open pins in whom there was no history of the accident and in whom symptoms caused by the pin were, for an unfortunate period of delay, attributed to some more humble cause. The following case, seen at the Bronchoscopic Clinic of the Massachusetts Eye and Ear Infirmary for removal of an open safety pin from the larynx, clearly illustrates this point.

R. N., a 7-year-old boy, previously perfectly well, while attending school suddenly choked, coughed and vomited. Sent home by the teacher, he immediately reported to his grandmother that he had swallowed a safety pin. She, being quite hard of hearing, failed entirely to grasp the significance of this story. On the return of the boy's mother, she found him quite hoarse and, presuming him to have a cold, summoned a physician. For the ensuing 2 weeks the boy was treated by three physicians for laryngitis, since he advanced no further information about the pin. The latter was only discovered when, after 3 weeks from the date of accident, a fourth consultant suggested an x-ray, which clearly showed the open pin in the larynx. The pin was removed by the method described below.

It is thus apparent that any physician called in such an accident must at least keep the possibility of foreign body, uncommon as it may be, in mind as a cause for sudden, unexplained deglutitory or respiratory distress. It is at least important, so far as infants and safety pins are concerned, to inquire whether a pin is missing, if such information is not previously volunteered. To this point of suspicion on the part of the attending physician, I have called especial attention in discussing accidental inhalation of nuts.<sup>2</sup> Fortunately, an x-ray film is an infallible diagnostic aid in determining the presence of an open safety pin, but its use must be preceded by the thought that a

foreign body may be present. In spite of this, numerous cases are on record in which one and sometimes more than one open pin have remained unrecognized in the esophagus, the symptoms being attributed to some gastrointestinal disturbance, and no consideration given to the true cause of the trouble.

With respect to pins in the air passages, as exemplified by the case cited above, hoarseness is an almost invariable accompaniment of a safety pin in the larynx, since the presence of the pin prevents accurate apposition of the vocal cords. If, however, the pin chances to reach the bronchus, the clinical course may be essentially asymptomatic, except for a slight cough. In both the larynx and the bronchus, respiratory obstruction is not usually a marked symptom. The actual encroachment on the airways by such a pin even in the larynx is not great, and strange as it may seem, the surrounding inflammatory reaction provoked by the presence of the intruder may be very slight. This is in marked contrast to the reaction to the presence of a nut in the bronchus, in which, besides acting as an obstructing ball valve, it is apt to set up a severe and aggravating inflammatory reaction, tending to occlude the airway completely.

Knowing of or suspecting the presence of an open pin in the throat, parents and physicians should, above all, refrain from any crude or traumatizing attempts to remove it. Such efforts will only succeed either in driving the pin still deeper in the throat or possibly in inflicting severe trauma to vital structures. This warning is given, notwithstanding the following letter received on the occasion of a previous similar and public admonition:

I was reading your lecture. When my girl was two years old she got a tin whistle in her throat. I was all alone so took her across my lap and shook and rubbed her. The whistle came across the floor. My doctor said I saved her life. My aunt's brother got a safety pin in his throat, open. She took a buttonhook and saved him. I would do the same thing again to my two grandsons today. You have to use what help is near.

A GRANDMOTHER OF THREE

Once the diagnosis of the presence of an open pin in the hypopharynx, larynx or esophagus has been made, the patient should be referred to some institution adequately equipped for the safe removal of such potentially dangerous foreign bodies.

#### REMOVAL

It has already been stated that methods for the removal of open pins in the air and food pas-

sages must be selected according to the particular problem in hand. Jackson,<sup>3</sup> in a recent textbook, lists sixteen different possible technics for removing safety pins. It is manifestly impossible for an endoscopist working in any but the largest endoscopic clinic to be master of such a multiplicity of procedures, and it has been my experience that in almost all cases reliance on a much smaller number of maneuvers, thoroughly studied and frequently practiced on a manikin or in the surgical laboratory, yields satisfactory results. Unquestionably, very unusual situations require specialized variations in technic, but the description of the following methods will, it is believed, prove adequate as a guide for removing the great majority of open safety pins encountered over a considerable period.

Preliminary to any attempt at removal, it is imperative to make a most careful roentgen-ray study of the patient, clearly establishing the locality of the pin and its relation to anatomic structures. From this study, it should be possible to ascertain, in comparison with a graded series of standard pins, the size of the pin in question. Still more helpful, if available and dependable, is an exact duplicate of the pin brought in by the parent or patient.

#### Anesthesia

The question of anesthesia has long provoked controversy and disagreement among leading endoscopists. Jackson,<sup>3</sup> backed by a wealth of experience, has persistently been an advocate of the policy of giving no anesthesia to children and only local anesthesia to adults. The merits of the various forms of anesthesia available for all endoscopic procedures are beyond the scope of this paper. It has been my experience, so far as the removal of an open safety pin is concerned,—particularly in the esophagus and in infants and very small children,—that there are more advantages than disadvantages accruing from the use of a general anesthetic. With foreign bodies in the larynx and in any patient in whom there is a question of respiratory embarrassment, I should counsel the avoidance of any form of general anesthesia. Otherwise, with appropriately sized instruments, with a competent anesthetist, and with the exercise of utmost gentleness of manipulation, I believe that the resultant relaxation of the esophageal musculature is an advantage that far outweighs any objection to general anesthesia.

#### Pins in the Hypopharynx

*Point down.* In the few cases in which the pin lies point down in the hypopharynx, the mechanical problem should not afford difficulty. Either

a laryngoscope or a small-sized esophageal speculum is used to expose the lower portion of the hypopharynx. The spring of the pin is viewed under direct vision and grasped with alligator forceps, preferably one in which the tips of the jaws carry a small projection. When these projections close over the spring of the pin, they do not fix it but permit it some latitude in lateral rotation, or what may be termed "togglng,"

FIGURE 2. *Method of Extraction from the Hypopharynx.*

*The keeper of the pin is grasped; this allows the pointed shaft to follow the line of least resistance.*

at the same time avoiding any tendency for an insecure grasp with possible slipping off of the pin. This togglng permits the pin, during withdrawal, to adapt itself to the pharyngeal wall and thus to find its way with the minimum of resistance. With the point always trailing, no trauma to the pharyngeal walls should occur.

*Point up.* In this position, it is folly to conclude that direct traction, unaided by laryngoscopy, is safe, even when the keeper is easily visible on inspection by direct depression of the tongue. The possibility that such traction will drive the pointed shaft into the pharyngeal wall must never be lost sight of, particularly traction applied without the aid of the laryngoscope and by the simple expedient of grasping the keeper with a curved hemostat.

There are in general two safe and feasible endoscopic methods applicable for pins in the hypopharynx with the point up. In the first procedure (Fig. 2), the keeper, usually the first portion of the pin seen on direct inspection with the laryngoscope or small esophageal speculum, is

grasped through the central lumen with the togglng type of forceps, great care being taken that the teeth of the forceps meet within the eye of the keeper and do not grasp either the distal or proximal margins. Gentle traction is then made, allowing the pin to rotate to the side opposite the point until the pointed shaft occupies a transverse position across the mouth of the hypopharynx. This location tends to occur because the point remains in contact with the hypopharyngeal wall and so acts as a pivot on which, because of the togglng action, the remainder of the pin turns. So long as the length of the pointed shaft does not exceed the width of that portion of the hypopharynx in which it lies, the pin may then be withdrawn without risk of further penetration of the pharyngeal wall by the point. No pressure should be made by the exposing laryngo-

FIGURE 3. *Method of Extraction from the Hypopharynx.*

*The lower end of the keeper shaft is grasped; this allows the pin to rotate. The tip of the laryngoscope guards the point. A — position of pin after "version."*

scope against any portion of the pin that must remain free to assume any position it seeks.

A modification of this method is applicable to pins in the hypopharynx that are of more than average size when it is believed that the pointed shaft might have difficulty in passing out through the pharyngeal diameter or when the pointed shaft is found deeply embedded in the mucosa or musculature of the pharyngeal wall. The shaft of the keeper is exposed to direct vision as far down as possible, preferably even as far as the spring (Fig. 3). An alligator forceps is then introduced parallel to and beside the laryngoscope,

but not passing through the lumen lest it obstruct the view of the exposed shaft. The latter is then grasped as close to the spring as possible and traction made laterally and upward, to displace the spring to the side of the hypopharynx away from the pointed shaft. At the same time, an effort is made to advance the lip of the laryngoscope in close proximity to the pointed shaft, and to hold it in contact with the latter as near the point as its engagement in the mucosa will permit. Thus, the lip of the laryngoscope tends to act as a fulcrum and also as a hindrance to any further advance of the point. With lateral and upward traction with the forceps, the

perfect, if possible, a reasonably satisfactory method and so to practice it in the laboratory as to render it dependable except, perhaps, on the rarest occasions.

For the last fifteen years, it has been my practice with pins in this region to make use wherever possible of the Mosher safety-pin closer. The original model of this highly ingenious instrument has well stood the test of time and in my hands is easier to manipulate than the later and presumably improved variations. Barring minor changes in the obliquity of the distal end and lighting equipment, I can see no reason to alter it. Its use depends on the principle of ad-

FIGURE 4. Method of Extraction from the Midesophagus.

A—the pin is grasped with toggle forceps passed through a Mosher pin closer; B—the Mosher closer is passed down over the keeper shaft until the spring reaches the transverse slot; C—the closer is rotated preparatory to pushing the pin downward with the pointed shaft impinging on the transverse slot, D—the pin is enclosed in the keeper and held by forceps ready to be withdrawn with the closer and forceps as a unit.

pin swings through an arc, the center of which is the edge of the laryngoscope. Thus is effected what Jackson<sup>3</sup> terms a "version" of the pin to the degree that the previously advancing point becomes converted into a trailing one, permitting ultimate safe removal by the spring or a point on the keeper shaft close to it (Fig. 3A). Once this method of fixation and traction is initiated, there must be no change in the relation of the laryngoscope or forceps lest this distort the mechanical principle and result in possible trauma.

#### *Pins in the Cervical and Thoracic Esophagus*

It is in the removal of open safety pins from this region that one encounters the greatest variability in technic employed by different operators and the expression of amazing ingenuity in the invention of specialized instruments. It is particularly for this reason that it seems wise to

vancing the lower end of the instrument over the keeper and keeper shaft of the pin, while the extended and angulated pointed shaft remains outside and slides through a narrow slot extending somewhat over 2.5 cm. from the distal end of the tube. The proximal end of this longitudinal slot joins a wider triangular-shaped and much shorter lateral slot. Since the keeper of the pin has first been securely grasped with forceps applied under direct vision through the tube and held fixed in this position, without the slightest traction, there is no tendency for the pin to move (Fig. 4A and B). As soon as the point of union of the longitudinal and transverse slot reaches the spring, further advance of the tube is stopped, and the entire tube—but not the forceps—is so rotated as to bring the transverse slot in contact with the pointed shaft of the pin (Fig. 4C). With the tube fixed in this new position, the forceps,

still grasping the keeper, is advanced, forcing the latter downward into the distal portion of the tube and at the same time pushing the pointed arm of the pin against the lower margin of the transverse slot. This results in forcing the pointed arm into the tube until, with further advance of the forceps, the entire pointed arm is sheathed within the tube and the point thus completely protected (Fig. 4D). It is in no way essential that this closure result in the actual entrance of the point within the lips of the keeper of the pin itself. So long as none of the point extends beyond the tube, it is sufficiently protected. The entire system—pin, forceps and tube—in this new relation may then safely be withdrawn through the mouth.

The following fundamental precautions must be rigidly observed if this method is to succeed:

The diameter of the tube or Mosher esophagoscope must be adequate to admit freely the keeper of the pin. Only if this is possible can the maneuver be executed. For this reason, it is of paramount importance to determine the size of the pin with which one has to deal. It is desirable but not imperative that the blades of the forceps permit toggling of the keeper, since it is thereby somewhat easier for the pointed shaft to find its way into the longitudinal slot.

Under no circumstances, once the keeper is thus secured, should any traction be made with the forceps. Unconsciously to make such traction while the esophagoscope is being advanced over the keeper is to risk perforation or penetration of the esophageal wall by the pointed shaft, a far more serious accident with pins in the esophagus than with those in the hypopharynx.

Care must be taken in the final advance of the forceps that the pin is not pushed so far down toward the distal end of the tube that the pointed shaft is permitted to escape from the end. In this event, all the work must be repeated. The moment that the spring appears beyond the tube end, further forceps advance must stop, since the point will already be adequately sheathed. It is in the method of determining the limit of the forceps' advance that one comes to the final and, in many ways, most important requisite, the fluoroscope. I am convinced that fluoroscopic control is absolutely essential in the execution of this method of safety-pin removal from any portion of the esophagus below the cricopharyngeus muscle. Sheathing can undoubtedly be accomplished without this aid, but the added safety is a factor that, I believe, goes far toward assuring success. The

best calculated and positive manipulation in the esophagus can sometimes go awry, and there is no better way to avoid such mischances than the utilization of the help from a competent radiologist, who can observe every technical step in the removal of an open safety pin by this method. At the Bronchoscopic Clinic of the Massachusetts Eye and Ear Infirmary, it is an inflexible rule that all such and many other esophageal and bronchial foreign bodies be removed under fluoroscopic guidance.

Even under the most favorable circumstances and with every possible help, it may not always prove feasible to adhere to the determination to remove an open safety pin through the mouth, even though it is admitted that it entered by this route. If, for any reason, the sheathing method does not proceed to a successful termination, it may be advisable to advance the pin to the stomach and there deposit it. This involves putting one's pride in one's pocket and a chagrining although perhaps only temporary loss of face. A foreign body in the stomach and an untraumatized esophagus are far better for the patient than peroral removal and subsequent mediastinitis. It is the opinion of most general surgeons that an open safety pin in the stomach, if not of undue size, will pass harmlessly through the remainder of the digestive tract without the necessity of any surgical intervention. Unquestionably, it may at times be necessary to remove from the stomach an open pin that, after a reasonable delay, refuses to pass through the pylorus, but this circumstance in my experience has been rare. Such pins in the stomach will not infrequently be found in the stool within twenty-four to forty-eight hours.

For those who dislike such deposition of the pin in the stomach, there is available the method of gastric version in which the pin, grasped by the spring from above, is carried into the stomach, allowed to reverse its position and then brought out, point trailing, through the mouth. With this method, I have had no clinical experience.

The foregoing description of sheathing an open safety pin applies quite obviously to those cases in which the pin rests point up. With the point downward in the lower esophagus, the problem is simpler, involving exposure of the spring by means of the esophagoscope, the grasping of the spring with forceps, preferably toggling, and the withdrawal, at least to a partial extent, of the spring into the lumen of the tube. Here again, although not indispensable, fluoroscopic guidance may be more valuable than one might at first suppose.

### is in the Respiratory Tract

*The larynx.* As already explained, an open safety or clasp pin lodges oftenest in the larynx, point . . . If the point itself is clearly visible above the . . . of the vocal cords in the anterior commissure, it is usually not difficult to grasp the keeper with alligator forceps passed through the laryngoscope and to slip the pin upward without engag-

firmly near the base of the epiglottis and presumably just above the pointed end of the pin (Fig. 5B). With the laryngoscope thus fixed, traction is made on the keeper, which is then withdrawn through the lumen of the laryngoscope, in the process of which the normal acute angulation of the shafts is expanded into a wide, obtuse angle or almost into a straight line (Fig. 5C). This

FIGURE 5 Method of Extraction from the Larynx.

A—the keeper of the pin is grasped by toggle forceps, while the tip of the laryngoscope protects the point; B—traction on the keeper is made while the laryngoscope prevents advance of the point; C—the straightened pin is withdrawn through the laryngoscope, with point trailing.

the point in the soft tissues. If, however, the point of the pin is engaged in the anterior glottic space below the point of approximation of the vocal folds, simple traction will be unsuccessful. Under these conditions, I have found the method of partial straightening of the pin through the larynx safe and satisfactory one. With the larynx exposed by the laryngoscope, the presenting keeper is grasped with toggle forceps, the keeper lying, already explained, in the sagittal plane (Fig. 5A). The tip of the laryngoscope is then held

principle presupposes that the point of the pin will not advance beyond the lip of the laryngoscope, so long as the latter is held rigidly in place, until the pin is straightened out. There is sufficient laxity of the interarytenoid space to permit the spring to rotate around the axis fixed by the laryngoscope. Even were the point to advance slightly beyond the lip of the laryngoscope, it is unlikely that any serious trauma would be inflicted in the region of the anterior commissure. With the point facing posteriorly, one might hesitate to execute

this maneuver, lest the party wall between the larynx and esophagus be perforated, but fortunately this accident is extremely uncommon.

*The bronchus.* In the event that an open safety pin of relatively small size with a necessarily less than ordinary spread passes through the larynx, it may come to rest in a main bronchus, oftenest just below the bifurcation of the trachea and usually with the point up. Such a pin could, of course, conceivably lodge in the

bronchoscope beyond the pin (Fig. 6A). The keeper is grasped with toggle forceps, and the bronchoscope slipped downward until the spring impinges on the more distal edge of the bronchoscope (Fig. 6B). The latter is then held firmly in place, and steady traction is made on the keeper, thus straightening the pin into the bronchoscope (Fig. 6C). The apparent risk of this procedure is greatly minimized by the fact that such bronchial pins usually lie with the point just

FIGURE 6. Method of Extraction from the Bronchus.

A—the pin is grasped with toggle forceps, preparatory to advance of the bronchoscope over the keeper; B—the keeper is drawn into the tube, with the lip of bronchoscope braced against the spring preparatory to straightening into the tube; C—the pin is straightened into the bronchoscope, with point trailing.

trachea, but if of sufficiently small size to pass the subglottic region, it is far likelier to descend and lodge in one or the other of the major bronchi. In my very limited experience with this situation, I have found the straightening method, somewhat as above described with reference to the larynx, to be satisfactory. It is first of all necessary to pass the bronchoscope into the invaded bronchus and visualize the keeper of the pin. The bronchoscope must be of sufficient caliber to permit, in much the same manner as the Mosher esophagoscope, the entrance of the keeper into its lumen. There is no question, however, of closure, since it is impossible, owing to the decreasing caliber of the bronchus, to advance the

proximal to the carina. As traction is made against the lip of the bronchoscope, the point tends to rotate across the carina and even into the orifice of the opposite main bronchus, thus affording it a temporary resting place until it is converted into a trailing point. As already stressed, it is of the greatest importance to know beforehand the size of the keeper and to utilize a bronchoscope the lumen of which is assuredly large enough to admit the keeper freely. In an infant, this necessity may provoke complications, since a sufficiently large bronchoscope may pass the larynx with difficulty and, later, resultant laryngeal edema may require tracheotomy. This, however, is not serious provided that the pin has been successfully

removed without trauma to the tracheobronchial tree. Fluoroscopic assistance in such a situation is not so essential as it is with pins in the esophagus, but may be of distinct assistance to the bronchoscopist.

### COMPLICATIONS

The complication most to be feared in connection with an open safety or clasp pin in the food passages is perforation of the esophagus. The wide and unyielding spread of the spring seems off hand to make this a likely occurrence in any case in which the pin is not removed immediately. Rather strangely, such preoperative perforations are quite rare, and open pins have been known to remain in the esophagus for weeks or months without perforation or serious local infection. The considerable mobility of the esophageal wall doubtless accounts for this fortunate circumstance. Hence responsibility for the definite development of alarming symptoms of perforation or mediastinal infection following attempted removal must usually be placed squarely on the shoulders of the operator, who can feel scant solace in the thought that the pin may have perforated spontaneously. Postoperative elevation of temperature, painful deglutition, a rising leukocyte count and definite roentgenographic evidence of an increasing prevertebral swelling with or without air in the tissues—any or a group of these symptoms strongly suggest the need for prompt consultation with a

thoracic surgeon, with strong probability that external drainage of the upper or lower mediastinum will be advisable. More detailed consideration of the indications for such surgery does not fall within the scope of this paper. Suffice it to say that impending tragedies have been averted by prompt resort to external drainage of an esophageal perforation.

### CONCLUSIONS

The open safety pin is a relatively common foreign body in the upper air and food passages. Early diagnosis is best assured by x-ray examination of any patient in whom such a foreign body is suspected.

Technics of removal vary with the location of the pin, but familiarity with one dependable method is more valuable than a theoretical knowledge of several. Fluoroscopic aid is indispensable in the removal of pins in the cervical and thoracic esophagus, and is a distinct aid with those in the tracheobronchial tree.

Evidence of a complicating esophageal perforation demands prompt consultation with a thoracic surgeon.

## ENLARGEMENT OF THE HEART\*

PAUL D. WHITE, MD †

BOSTON

THERE has been a great deal of talk about congestive heart failure during the last few years—indeed, to the extent that it has taken the limelight of medical interest, so far as the heart is concerned. Important as it is, however, it is far less vital and should receive less attention by the medical profession than two other cardiac problems. The relatively greater significance of the first of these, the causes of heart damage or strain, is readily and widely admitted, but the second is often neglected and indeed sometimes forgotten, namely, heart size—whether or not there are any other abnormalities, such as symptoms, murmurs and arrhythmias.

Two hundred and sixty-two years ago, Théophile Bonet published a fundamental collection of autopsy reports, the *Sepulchretum*, which was

critically reviewed and amplified in a sort of third edition by Morgagni nearly a century later, under the title *De Sedibus et Causis Morborum*. In the original edition in 1679, there were a number of cases showing enlargement of the heart, one of these patients had suffered from shortness of breath that before death had been routinely ascribed to pulmonary disease, which was not found post mortem. The association of a serious symptom with a large heart was spoken of with surprise by the observers of that case and was evidently the beginning of the realization of the importance of cardiac enlargement. A few decades later, in 1728, there was published a book, in large part on this subject, written by Lancisi, physician to Pope Clement XI, it was entitled *De Motu Cordis* [following the post Harvey tradition] *et Aneurysmatibus*, which meant large hearts as well as large aortas.

Thus, quite rightly, the first cardiac abnormality

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1941.  
†Physician, Massachusetts General Hospital; lecturer in medical history at Harvard Medical School.

of consequence to be described and studied in pathology and clinical medicine was enlargement of the heart. With the advent of auscultation, however, medical interest was turned away from heart size, on which percussion, already introduced, was unable to focus attention, and concentrated for a century or more on heart murmurs, which were too often interpreted as evidence of valvular disease. The textbooks for many decades were filled with chapters on every possible valve defect, only a few persons, like Mackenzie, trying to redirect attention to other cardiac findings, after the turn of the century. At last, cardiologists are approaching a saner and wiser viewpoint, although I dare say they are still simply in the middle of the process of proper cardiac orientation. It is this revolution and evolution in cardiovascular knowledge that has rendered a cardiologic vocation absorbing and satisfying for those who were so fortunate as to enter that field two or three decades ago.

The first of the problems of heart size is the most difficult of all, namely, the range of the normal size. It has been left to the last to study, for, fundamental though it is, it has not appealed to the pioneers who have been unearthing, with almost every spadeful, nuggets of interesting, spectacular and unusual pathologic conditions of the heart. I have been as guilty as the next man in this respect, witness to which is the record that my laboratory still holds in medical literature of enormous heart volume—seven times the normal. Now at last, except for a few who have patiently tilled the field for some years, cardiologists are turning to the more vital problem of the determination of the beginning of cardiac enlargement in any given case.

What is the normal heart size, and how can it be ascertained in a particular person? Even the anatomist, pathologist and anthropologist cannot limit the heart weight and volume for the normal person within a narrow range. Roughly, the weight of the heart has been considered normally to average 0.5 per cent of the body weight, but this is a very imperfect estimate indeed. Body build and other hereditary manifestations that have not yet been worked out are undoubtedly important correlative factors; the aid of anthropologic data is needed to secure greater accuracy of fundamental measurements, and this aid is only now beginning to be sought.

With this difficult enough problem to begin with, one now must face the additional difficulty of the clinical determination of heart size. Three methods are available. First and simplest and often quite accurate is the position of the cardiac

apex impulse by palpation. Sometimes this is easily determined, sometimes only with difficulty, and sometimes it is impossible. In those cases in which the maximal apex impulse is found in the fifth intercostal space within or on the left mid-clavicular line, one can be quite sure that there is no significant cardiac enlargement. In such cases, it is still essential to percuss the position of the left upper border in the third and fourth interspaces, — and this can be done in most cases with reasonable accuracy, — to determine if there is undue prominence of that part of the heart, a finding common in cases of mitral stenosis or cor pulmonale with an enlarged right ventricle but with the apex impulse not far from the normal position.

Next, a word is due about percussion. Inaccurate and disappointing as this method of examination may be in many cases, in comparison to x-ray study, it is often a useful procedure in many patients when x-ray examination is impracticable or not immediately possible. There are many such cases, and if one sits back with folded hands complaining of the inferiority of percussion to the x-ray film, one will miss valuable evidence of heart size that may be obtained only by percussion when the apex impulse is felt with difficulty, or not at all, and when x-ray examination is not available. It is necessary to acquire skill in percussion, which cannot be learned overnight. Most of those who scorn percussion do not want to bother to learn the technic or through long neglect have lost all confidence in it. Even though I fluoroscope each one of my patients in my office, I percuss the chest first and thereby control my percussion findings and keep up a certain practice that proves helpful when I encounter patients elsewhere, as at home. I can recommend this procedure.

Too much confidence about heart size, on the other hand, is often yielded to an x-ray report, — not that the x-ray picture per se is not correct, although even its accurate transcription and original interpretation need a check, for which more than once physical examination has served me well, — but deductions from measurements of the x-ray heart shadow must be made in borderline cases only with the greatest care. Here, too, there are wide limits of the normal, even for the same height and weight and age — so wide in fact that a good many competent and experienced roentgenologists do not bother even to make any measurements unless requested. Other roentgenologists furnish a long list of measurements of diameters, arcs, area and even volume; these are often interesting but far less valuable than an actual view of the x-ray film itself, or best of all, of the subject

in the flesh under the fluoroscope. There are too many imponderables for one to have confidence in a few ponderables, if overmuch is made of them. My own attitude is a compromise between these two extreme points of view. I favor those who scoff at emphasis on detailed measurements, and yet, poor as they may be, the measurements to my mind are better than none, for x-ray films may be lost or difficult to secure at any given moment for detailed study or comparison with previous records, and figures, rightly or wrongly, mean more to me than mere statements of normal heart size or of slight, moderate or great enlargement.

Just a brief word, before leaving x-ray heart study, about the best measurements to use. Combinations and correlations of the various diameters have been introduced, and the heart volume has also been roughly measured, but none of these procedures are practicable for routine use, because of various difficulties of technic or of wide scatter of the normal range. Three methods in common use are equally applicable to orthodiagraphy and to seven foot films, and are satisfactory in their routine employment, when one remembers that the heart shadow is larger by nearly 10 per cent in the seven foot film than in the orthodiagram. The commonest method, but one that should be discarded because its range of the normal is the widest, is the so called 'cardio thoracic ratio,' that is, the division of the transverse diameter of the heart by the internal transverse diameter of the thorax, here the normal range is tremendous, from 33 to 55 per cent. The other two methods, both open to objection but the best for routine use, are the correlation of the transverse diameter of the heart shadow with height, weight and age, according to the Hodges-Lyster formula, nomogram or slide rule, and the correlation of the area according to height, weight and age. There are special advocates of both and since the measurement of the transverse diameter is much simpler and quicker technically, I am at present using it with the help of a simple slide rule. It is as quick as and better than the cardio thoracic ratio, which I have recently discarded. Actually, however, for reliance one needs something better than anything as yet available.

The most awkward dilemma is an inability in many cases to detect the presence of slight cardiac enlargement, an early sign of serious heart strain and therefore an essential thing to know in any cardiac patient. The range of normal is so wide that any case may change from a small normal heart size to a large normal heart size without one's realization of the fact unless one has early careful measurements of that particular heart to begin with.

Formerly, cardiac enlargement was regarded as evidence that the heart was strong and compensating for whatever strain was present, but it has gradually become realized that a large heart is a bad sign and evidence that the myocardium is not a normal healthy muscle and that it is no longer able to resist the strain. It is an indication that more and more enlargement is likely to follow, resulting in myocardial failure of the congestive type, unless the strain can be eliminated. In fact, any cardiac enlargement is already evidence of some failure of myocardial strength, although not at first of the grade to result in congestion. Slight and moderate grades of increase in heart size may persist with little change for years, however, and are not to be viewed with immediate apprehension. Nevertheless, they are not good signs, and important trouble threatens if marked enlargement is found or if the size steadily increases under observation for a relatively short time.

Enlargement of the heart may be due to acute dilatation, to preponderant hypertrophy or to both hypertrophy and dilatation of comparable degree. The best theory of its onset is that it starts as an overstretching or dilatation of the myocardium and that work hypertrophy is in large part a reaction of the heart muscle to injury and a failure of the myocardium to return to its original size. Little by little, this stretching in many cases goes on until the heart becomes very heavy, although often with relatively little dilatation of the heart chambers, and the process accelerates to a state of clinical myocardial insufficiency from which congestive heart failure results.

There has been a return to the old time diagnosis of acute dilatation of the heart, once applied indiscriminately and often to the wrong patients, then two or three decades ago abandoned disdainfully, but now acknowledged as a correct appellation for certain cases. Four conditions are occasionally responsible for a fairly acute dilatation of the heart, two of which—namely, severe acute rheumatic myocarditis and excessive heart rate in paroxysmal tachycardia—affect both ventricles, the third, acute massive, myocardial infarction, involves the left ventricle primarily, and the fourth, massive pulmonary embolism, involves the right ventricle (the acute cor pulmonale). The acute dilatation may precipitate congestive failure and death, it may clear up almost or apparently completely on subsidence of the acute strain, or it may, as in many cases of acute rheumatic and acute coronary heart disease, leave permanent enlargement of the heart, consisting in both dilatation and secondary hypertrophy, which may in chronic rheumatic heart

disease be ascribed wrongly, in toto at least, to coincident valvular deformity.

Some hearts, especially those under the strain of systemic or pulmonary hypertension and of aortic stenosis, show at first and for years preponderant hypertrophy, dilating appreciably only at the time of final failure. Others, especially those with free aortic regurgitation, show much dilatation at an early stage and also the highest degrees of hypertrophy; the heaviest and often the most voluminous hearts belong in this group and have been labeled "cor bovinum." The record-breaking hearts in volume, however, are those with mitral valve disease and auricular fibrillation in which the left auricle and often the right ventricle and right auricle become enormous, whereas the left ventricle is normal or actually small.

In most cases of cardiac enlargement, the strain is left-sided, from systemic hypertension, aortic valve disease or myocardial infarction, and the left ventricle consequently enlarges first and sometimes is the only heart chamber to do so. But very frequently it becomes incompetent, and then, in order, first the left auricle, next the right ventricle and finally the right auricle become enlarged. It is enlargement of the left ventricle that increases the heart weight preponderantly; that of the left auricle displaces the greatest space.

The right ventricle is far oftener enlarged than cardiologists formerly realized, chiefly because attention has been distracted by the much more obvious enlargement of the left ventricle, and because the right ventricle has been neglected, even by the pathologist. Another reason is that when it is enlarged alone, with little or no dilatation, it may escape notice clinically even on the most careful x-ray examination, as happened in a case of extensive pulmonary emphysema recently considered at a clinicopathological conference at the Massachusetts General Hospital, in which at autopsy the right ventricular wall measured 7 mm. in thickness (normal, 3 to 4 mm.); it is quite probable, however, that an electrocardiogram would have afforded the only clue, but an essential one, in the form of a considerable degree of right-axis deviation. Finally, it should be remembered that the commonest cause

of enlargement of the right ventricle is failure of the left.

Many different factors may cause cardiac enlargement, some extracardiac, like anemia and myxedema, and some intracardiac, like rheumatic myocarditis, myocardial infarction and valvular disease. In either event, the strain may be largely acute and temporary, and the enlargement may subside; but also in either event, the strain may persist and the enlargement may become permanent. Chronic enlargement is, of course, most commonly due to intracardiac disease and systemic hypertension. Quite often, particularly in older patients, more than one factor may be active at the same time. One condition, chronic pericarditis, was once wrongly blamed as a cause of great cardiac enlargement; a pericardial effusion can of course simulate a large heart, but it really acts like occasional chronic pericarditis to constrict the heart and so to make it smaller.

The prognosis of cardiac enlargement is quickly and fairly well summarized in the observation that "the larger the heart, the worse the future." Although there are exceptions, this rule holds if other things are equal.

Finally, the treatment of cardiac enlargement is twofold: first, relief of the underlying strain, which is not always possible directly, but which one can often help a great deal by reducing other strains of daily life; and secondly, the optional routine use of a daily ration of digitalis to help to prevent or retard further cardiac enlargement and failure. It seems reasonable to give 1 or 1½ gr. of digitalis daily for this purpose; the value of this drug has not yet been proved, and it will be difficult to prove.

\* \* \*

Cardiac enlargement should be suspected in patients whose hearts are under strain, even though they are free of symptoms; it is possible to do more good at an early stage than after heart failure has set in. On the other hand, it is equally important not to establish cardiac neuroses thereby, and especially not to mistake for cardiac enlargement a heart size that is on the borderline of normal unless undue heart strain is or has been present.

## NUTRITION IN WAR\*

ROBERT S. HARRIS, Ph.D.†

CAMBRIDGE, MASSACHUSETTS

DURING recent years, this nation has unquestionably been living on a dietary borderline in ability to supply the nutritional factors necessary for physiologic health. Deficiency disease is endemic in this best-fed nation because more than 40 per cent of the families do not have the money to buy food for an adequate diet, because those who have the money do not have the knowledge, interest or diet habits to buy the proper foods, and because foods have been refined, processed and canned without regard to the effects on nutritional factors. As times goes on, it is being demonstrated experimentally, clinically and in the daily life of the people that the majority are knowingly or unknowingly ailing from the insidious effects of deficiency disease.

Perhaps the most important cause of these deficiencies is a too-strict adherence to the precept "Cleanliness is next to Godliness," for Americans have insisted that their foods be whitened, polished and refined. In removing the color from foods, they have unconsciously destroyed the precious compounds on which, as an evolving race, they developed a dependence.

Eight decades ago, the roller-mill process for flour manufacture was invented, and today all white flour is made by that process. Jolliffe<sup>1</sup> has calculated that, to obtain the thiamin lost by consuming this white flour instead of the stone-milled flour of one hundred years ago, one would have to consume each day, in addition to the ordinary diet, about 1½ pounds of fruit, 1½ pounds of potatoes, 2 pounds of other vegetables and 1½ quarts of milk. Because it is difficult to increase one's food intake by so large an amount, and because such a procedure would be expensive, population groups with low incomes have suffered most from the refinement of the dietary and show the highest incidence of deficiency disease. The poor are of prime importance in considering measures to eliminate this condition, for those in higher economic brackets can more or less successfully, but not with certainty, make up for the losses caused by refinement by consuming more fresh vegetables and fruit.

The amount of bread consumed by a community

is usually in direct proportion to its economic status, for bread is the food of the poor. It was fundamentally sound, therefore, when the Committee on Food and Nutrition of the National Research Council was organized last fall, that its first action<sup>2</sup> was to decide the vitamin and mineral potencies that bread and flour should have to make these staple foods, which together constitute one fourth of the average calorie intake, carry their rightful nutritional quotas. Bread will become a staff of life on which man can again lean for true nourishment.

It is expected that cereal food products will be similarly enriched, and that the slight cost will be absorbed by the manufacturers. It is hoped, also, that the Committee on Food and Nutrition will continue to catalyze improvements in the basic foods of the poor, especially sugar and fats, and to encourage the consumer to purchase those inexpensive foods that will give him the most for his food dollar.

The problem confronting this committee is to see to it that the foods most readily available, the staple foods, are so nutritious and still so inexpensive that it would be exceedingly difficult for a person with little knowledge of nutrition to select a diet that would be deficient over a reasonable period.

Why is this especially significant at this time? Because an ill-fed nation is a sick nation.

Drummond and his group,<sup>3</sup> for example, made a comparative study of the life history of two groups of rats, one of which (483 animals) was maintained on what they called an "adequate" diet and the other (556 animals) was fed a diet providing a suboptimal intake of the vitamin B complex, the chief defect being that of vitamin B<sub>1</sub>. The life span was shortened, reproduction was impaired, and the incidence of gastrointestinal lesions was definitely increased (Table 1).

In similar experiments, McCarrison<sup>4</sup> apparently used a more adequate diet than Drummond, for he noted no gastrointestinal disorders in rats, rabbits, dogs and monkeys fed on this diet, whereas animals on a diet deficient in minerals, vitamins and proteins, and identical to the dietaries of a large mass of people, showed some gastrointestinal or organic disorder, usually several. Numerous other experimental and clinical results clearly indicate the great value of good nutrition and lead one to ask whether many of the maladies of to-

Associate professor of nutritional biochemistry, Massachusetts Institute of Technology.

day are the result of malnutrition and under-nutrition.

At the beginning of this century, it was thought that nutrition consisted in supplying calories for fuel, protein for muscle formation, water and a

\*Evidence of human needs is fragmentary.

It is now realized that nutrition is much more involved, and that more than three dozen substances and elements are required for normal physiologic functioning (Table 2). Each of these substances must be supplied in adequate amounts else deficiency disorders will result.

Nutrition of Armed Forces

Since the majority of the American people have minor nutritional ailments and a very substantial minority are definitely deficient in several nutritional factors, a good proportion of the men entering military service are undernourished. They are being given nutritionally balanced diets definitely superior to those on which they lived at home. One can therefore expect an improvement in the health, vigor and mental and physical stamina of these men. Military authorities are keenly aware of the importance of sound nutrition in preserving

the morale of the men, and they are constantly being advised by the best medical and nutritional experts in an effort to make the American soldier and sailor the best fed in the world.

The value of good nutrition to a nation at war is shown in the recent reports by Williams and his co-workers,<sup>5, 6</sup> who found, for example, that, in an experimental group, a diet deficient in thiamin produced moodiness, sluggishness, indifference, fear, depressed mental states, mental fatigue, dizziness, backache, insomnia, anorexia and physical fatigue. Morale and stamina cannot be expected of thiamin-hungry troops or populations.

The German high command has long studied the problem and has made painstaking preparations lest the present war be finally lost owing to the malnutrition of the German troops and peo-

ple. In World War I, malnutrition was a powerful factor in leading the Central Powers to seek an armistice. The food blockade of that war was so effective that starvation and its accompanying deficiency diseases were rampant in the general population. The advances that have been made in nutritional science since 1918 have been so great as to make it almost impossible to blockade the Nazi nation. All the important vitamins man needs can now be synthesized within Germany at little cost.

Today, the American manufacturer of food or vitamin products can purchase these vitamins for so little that a daily optimum costs less than 12 cents (Table 3). If the Government were to supply a population of 50,000,000 with these needed vitamins, the basic cost would be only \$206,000,000 yearly. Since these current prices in America are undoubtedly higher than those in Germany, it is evident that the Nazi command can easily supply sufficient vitamin supplements to protect the German armies and people against vitamin-deficiency disease, especially since a goodly fraction of the vitamin requirements can be contributed by rationed foods and ersatz.

Although vitamin starvation had much to do with the defeat of the Central Powers during World War I and would likely not be a factor in the defeat of the Axis in the present conflict,

protein starvation may be a significant factor. Calories can be obtained from many kinds of foods, vitamins can be synthesized in the chemical laboratories, minerals can if necessary be provided in the form of inexpensive tablets, but the protein requirements of a people cannot be met without good foods. The constituent aminoacids of proteins are needed for the formation and replacement of muscle tissue, and the special functions of many of these aminoacids cannot be performed by any other compound; only a few of these acids can be synthesized cheaply by the chemist.

A nation at war must have adequate supplies of good proteins if it is to survive. Therefore, foods rich in excellent protein (meat, milk powder and cheese) are today preferred for shipment to England.

The proteins of plant tissues are generally inferior to those of animal tissues because they are deficient in one or several of the essential aminoacids. It is, of course, possible to combine plant proteins in the dietary or in food mixtures so as to obtain adequate amounts of these aminoacids, but this requires special knowledge.

It has been authentically reported that the German forces, in garrisons and in active warfare, are living on dried foods and dried food mixtures. During the last ten years, the German government has fostered considerable research and developed methods for dehydrating foods without destroying nutritional factors and changing the taste. Without doubt, Germany stands far in advance of other nations in this vital field of food technology, which has not had the proper development in this country. The Nazi armies can be fed with tasty, nutritious, dehydrated foods, which require no refrigeration and are one fifth as bulky as ordinary foods. The rapid maneuvers and advances of the *Panzer* divisions in recent battles would have been difficult without this simple method of feeding.

Furthermore, in these rations, plant proteins rather than animal proteins have been used. It would be difficult to supply animal proteins during a long war, for the fodder needed by the livestock cannot be imported. For many years there has been an intensive planting of soybeans in the Balkans, in Bessarabia and in Germany. This interesting legume, long a staple food in the Orient, will grow on a variety of soils, requires little attention, and yields a food protein the important aminoacids of which approximate, in variety and proportion, the proteins of meat, milk and egg. Although considerable reliance is being placed on soybean protein, it is not certain that enough is being produced to meet Axis needs.

But this would be of no consequence, since one can be sure that the Nazi command will allow protein starvation to appear in the conquered nations and use their foodstuffs in feeding the Nazi armies and the German population.

Although it is my belief that the Axis will not be starved out of this war, there is a grave possibility that England will be counterblockaded into starvation: protein starvation, vitamin starvation and, eventually, calorie starvation. Britain has long been an industrial nation, importing raw materials and exporting manufactured goods, meanwhile relying on importations to supply 40 per cent of her food. She has lost several neighboring islands from which important quantities of vegetables and dairy products have been received in the past. She could not import enough fodder for her pigs, poultry, sheep and beef cattle, and has slaughtered many.

However, Britain has increased the number of milk cows so that an unrestricted amount of milk will be available to nursing and expectant mothers, to young children and to hospitals. Over 2,000,000 acres of grassland have been plowed up in response to a bonus of £2 per acre and planted mostly with grains (barley, oats and wheat). British leaders have stressed the point that malnutrition can be avoided with sufficient milk, vegetables and potatoes, and that starvation can be prevented with sufficient bread, vitaminized fat, potatoes and oatmeal. Imports of fats, sugar, dried fruits, frozen meats, canned meats, canned tomatoes, milk powder and cheese have been preferred, for these foods have high-calorie content per ton of shipping space, contain fine proteins and critical vitamins, and supply the special needs of the British people.

Foods such as meat, fats, butter and sugar have been rationed along with many nonessential food items. Any war involves a marked simplification of the foods of the people, with an accompanying loss in palatability and richness and a limitation of choice. There is evidence of reduction in body weight in some sections of the population. So long as this restriction is not great, the rationed peoples may be well off, since they report that they feel better. Severe restriction would be serious since, even in normal times, one must consume more than 1900 calories as food daily to obtain needed vitamins. The best choice of foods supplies less than three quarters of the required daily vitamin needs, with the possible exception of ascorbic acid. Thus, adults have a choice between deficiency disease and gluttony. If one can judge from the appearance of the adult population, they are choosing gluttony—the better choice under the circumstances. Is there not some rela-

tion between the good nature of the fat man and his better nutrition?

Rationing of food is not new; in fact, it is an integral part of planned economy. It need not work hardship on a people or adversely affect its morale. The poor have always been rationed, for poverty limits their choice of foods. Furthermore, since the people of a warring country are now truly in the front lines, they must be ready to resign themselves to the restrictions and methods of the soldier, even to the extent of eating concentrated food mixtures.

It should be pointed out that concentrated mixtures consist of several foods, cooked separately, blended and mixed; they are not ersatz in any sense, since only water is removed. That is all that can be done, because one cannot concentrate the 3000 calories or the 100 grams of protein that an adult needs daily. Test-tube feeding or capsule feeding is the invention of the newswriter, for adult man cannot be fed on less than  $1\frac{1}{3}$  pounds of concentrated foods daily.

### *Feeding the Population in War*

Research has shown that visual acuity, mental and physical health, morale and endurance may be impaired by nutritional deficiency. It is therefore imperative that workers connected with defense industries be well fed. It may be advisable to imitate England's soup kitchens by feeding the workers in these vital industries nutritious mid-day meals. Field tests have shown that the improvement of substandard diets in groups of workers results in increased output and a reduction in accidents.

One of the most important functions of the Government is the school-lunch program, which endeavors to feed needy children with surplus foods. In the present war, this program should be extended to include all undernourished children and to improve the lunches so that an adequate diet will be assured. The effect of a continued program on the health of these children and on their future usefulness to themselves and

others cannot be predicted too optimistically. Clinical experiments have shown its advantages.

Some method will have to be devised to care for the remainder of the population who cannot afford an adequate diet. Until then, the admirable Food Stamp Plan should be extended. Certain foods now purchased under this plan may soon lose their status. In fact, it appears that wheat is the only true surplus, and efforts should be made to curtail its production. Soybean, peanuts and similar foods of superior nutritive value should be grown in its stead.

### *Postwar Problems*

When the present conflict is over, there will be millions in various degrees of starvation who will need to be fed. There are millions today in this condition, but they cannot be reached. One can only hope that they will survive to the armistice. Hundreds of thousands will undoubtedly perish, the victims of disease resulting from their nutritional deficiencies. Those who survive may long carry the scars of their starvation, possibly into future generations. In looking ahead to the day when these unfortunate people may be fed, groups are anticipating the needs and devising a program to fill them.

\* \* \*

This is a critical and unhappy era. We can properly feed our own people and assist in the feeding of our valiant democratic allies. Britain must not be starved into submission. When the war ends, it will be our duty to help in the feeding of unfortunate peoples made destitute by war. This is the challenge on the food front—and we must meet it.

## MEDICAL PROGRESS

## ARTERITIS: DISEASES ASSOCIATED WITH INFLAMMATORY LESIONS OF THE PERIPHERAL ARTERIES\*

SONIA WEISS, M.D.

BOSTON

BY usage, the term "arteritis" refers to inflammatory conditions of the arterial vessels other than the aorta. Although in recent years significant advances have been made in the knowledge of arterial diseases characterized by inflammatory reactions within and without the vessel walls, this group of disorders still represents a difficult and confusing problem to many physicians. This report discusses only the more important conditions.

To understand the arteritides, consideration of the following facts is essential:

The arteries, like other organs, respond to many pathogenic agents, but with limited types of physiologic and tissue reactions. Several noxious agents of varied character often produce identical types of physiologic and morphologic vascular changes. For example, the same type of acute arteritis can be induced by infections, transplanted homologous adrenal glands, vaso-spastic drugs and exposure to cold. Hence, from a given type of histologic reaction alone, conclusions about the specificity of the pathogenic factors cannot necessarily be drawn.

The same type of arteritis can be associated with more than one clinical picture. Therefore, the morphologic knowledge of these diseases should not be confused with the clinical aspects of the problem. It is only recently that the clinical features have been adequately studied. In the past, interest has been mainly morphologic.

Acute arteritis is not always of infectious origin, because, as in other tissues, infection is but one of the causes of inflammation. Thus, persistent spasm, like that induced by ergot, causes an acute arteritis that is identical in morphologic composition to that caused by certain virus diseases.

During the healing stage, acute arteritis usually changes into fibrous and degenerative lesions. Again, the characteristics of the healing process

are usually the same in a number of diseases affecting the arteries. Arteriosclerosis is therefore merely the chronic tissue response to several different types of persisting noxious stimuli.

Various types of injury to the endothelial layers of the arteries are apt to be followed by thrombosis. Thromboangiitis obliterans is accordingly the result of several types of arterial disease.

Although cellular reactions in the myocardium, — called "Aschoff's bodies," — verrucous endocarditis and thickening of the cardiac valves and of the chordae tendineae occur particularly often in rheumatic fever, these cardiac lesions are not absolutely specific of this disease alone. They occur also in certain other conditions associated with affection of the arteries, skin, serous membranes and joints.

## PERIARTERITIS NODOSA

Arteritis associated with perivascular reactions occurs under many conditions. Thus, disseminated lupus erythematosus, dermatomyositis, typhus fever, rheumatic fever, multiple sclerosis and chronic pyelonephritis can be associated at times with localized arterial lesions like those of periarteritis nodosa. Periarteritis nodosa, however, in a *clinical sense*, as originally described by Kussmaul and Maier,<sup>1</sup> refers to a chronic systemic disease of obscure origin and, usually, with a serious prognosis. At present, about 350 to 400 cases of periarteritis nodosa have been reported in the literature. In only 50 or 60 cases, however, has the diagnosis been made clinically. Now that the clinical aspects of the disease are becoming crystallized, this number may be expected to increase rapidly.

From an analysis of the literature, the following general facts emerge. The disease is probably not so rare as observers have thought, and is three to four times commoner in the male than in the female. It can occur at any age, cases having been reported as early as three months and as late as seventy-eight years.<sup>2</sup> It usually occurs between the ages of ten and forty. The disease is not invariably fatal, and it is probable that the prog-

All articles in this series will be published in book form in the current volume of *Medical Progress Annual 1949* (Springfield, Illinois: Charles C. Thomas Company, 1949), \$4.00.

<sup>1</sup>Professor of the Theory and Practice of Medicine, Harvard University, physician-in-chief, Peter Bent Brigham Hospital.

nosis will improve, when the disease is oftener recognized clinically. The clinical picture varies strikingly, depending on the distribution, severity and persistence of the vascular lesions. Practically any organ can be affected and can be the source of symptoms or signs. It is consequently essential that in patients with bizarre and obscure symptoms suggesting infectious, rheumatic or cachectic disease the possibility of periarteritis nodosa always be considered. The onset is usually gradual. Remissions, long intermissions and exacerbations are common. If fever, cutaneous or subcutaneous nodules, aneurysms of either the large or small arteries, neuritis, asthma, cardiac and abdominal symptoms, pain in muscles and joints, and eosinophilia are present, the clinical diagnosis is more suggestive, but it must be realized that these so-called "characteristic features" are often absent entirely or for a long time. The nervous system is involved more frequently than is usually suspected. Arterial hypertension is present in only a small percentage of the cases, and this depends on an ischemic involvement of the renal arteries. The renal arteries, on the other hand, are frequently involved, although there is no hypertension. The value of recognizing the skin manifestations lies in the fact that such recognition makes diagnosis of the disease possible by biopsy. The veins, as well as the arteries, are occasionally affected.

In 1936, Spiegel<sup>3</sup> reported 17 cases and discussed the clinical aspects of the disease. She emphasized the fact that 7 of the 17 patients suffered from recognized prodromal illness of a "banal" type, such as acute tonsillitis, acute sinusitis and sensitization asthma, which then — without any intervening period of good health — merged with symptoms attributable to periarteritis nodosa. Scarlet fever of atypical form occurred in 2 other patients in the two months preceding the appearance of arteritic symptoms.

In 11 patients, abdominal pain was the first symptom attributable to the vascular lesions. Almost simultaneously, 5 suffered from arthritic pain, and 2 others had cardiac and nephritic symptoms. One suggestive diagnostic association was the combination of abdominal pain and apparently unconnected symptoms such as arthritis, nephritis and cardiac insufficiency. All the 15 cases with post-mortem studies showed cardiac involvement. Twelve had lesions of the coronary arteries of varying degree, and 4 had Aschoff bodies. One patient presented the clinical characteristics of an indeterminate type of verrucous endocarditis. Periarteritis nodosa of the pulmonary arteries was present in 5 cases, and it is of interest that in 6 there were pulmonary lesions not directly depend-

ent on arteritis. Pleural pain, asthma and typical bronchopneumonia may be clinical manifestations. In some of the patients, the roentgenologic findings suggested bronchopneumonia or small pleural effusions. It is of interest that in Spiegel's series 7 patients had surgical complications because of vascular lesions of the gastrointestinal tract. Hemorrhagic pancreatitis occurred in 3 cases. As many as 8 patients had neurologic symptoms; in 6, there was a clinical impression of encephal meningitis. The lesions indicated productive perivascular and meningeal reactions.

One or more of the following lesions occurred in 12 patients: erythematous macular papules, purpura, urticaria, herpes, edema, pulsatile nodules and white-centered petechiae. Retinal exudates, neuroretinitis and thinning of the retinal arteries occurred in association with renal involvement. One patient showed a characteristic nodule of the choroid on microscopic examination. Twelve patients had polyserositis. The leukocyte count reached 54,000 in 1 patient; polymorphonuclear leukocytes were predominant, although eosinophils and monocytes were also noted.

Leishman<sup>2</sup> has analyzed the clinical features of the cases reported in the literature. The symptoms and signs in order of frequency are as follows: fever (100 to 101°F.), weakness, albuminuria, cylindruria (hyaline and granular), leukocytosis, anemia, tachycardia (out of proportion to the fever), abdominal symptoms, polyneuritis, polyserositis, edema, cutaneous lesions, cardiac signs, enlargement and tenderness of the liver but not the spleen, respiratory symptoms and albuminuric retinitis.

More recently, Grant<sup>4</sup> has made an excellent study of periarteritis nodosa. He points out that the condition is less acute and less frequently fatal than is generally thought. Thus, of 7 patients in whom the disease was clinically diagnosed in 1937, only 3 died in 1940. He studied the characteristics of the vascular lesions and described them as a necrotizing arteritis or a hyaline or fibrinoid necrosis of the arterial wall, with surrounding inflammatory reactions. The necrosis affects mainly the inner part of the media and the subintimal regions, although the whole thickness of the wall may be involved. Either a segment of the arterial wall or its entire circumference may be affected, but commonly only short stretches of the vessels are attacked. The points where the smaller arteries branch off are particularly susceptible. The portions of the artery involved become disorganized, and the internal elastic lamina breaks up, with the result that aneurysms may form. Hemorrhages may occur within the arterial walls or in the sur-

rounding tissues. Thrombi often form within the vessels. The adventitia and surrounding tissues may be swollen or may, on the other hand, show little change. The type and degree of cellular reaction varies considerably, depending on the cause and the stage of the disease. In some cases, the histologic picture is almost that of purulent inflammation; in others, there is but a slight reaction. Usually, the reaction is subacute and contains polymorphonuclear and mononuclear cells, lymphocytes and plasma cells. Giant cells are present in some cases, and eosinophils may occur. In some cases, the arterial lesions may heal, forming granulation and scar tissue, with the result that the wall becomes thickened and the lumen narrowed. No features distinguish this healing process from other types of healing or healed arteritis.

The lesions often develop in crops. Usually, the small arteries and arterioles are affected. The larger arteries become involved indirectly through their nutrient arteries. It is relatively rare for the lesions to be visible to the naked eye. Because often only a small stretch of the artery is involved, it is advisable to examine the excised tissues in serial section, not to miss the affected vascular areas. Rarely, the veins are also affected. The arteries of the heart, kidneys, gastrointestinal canal, pancreas, liver, spleen, skeletal muscles, skin and central nervous tissue are usually the seat of the disease. The facts that necrotic foci of the skin and the myocardium can occur without vascular lesions and that vegetations may rarely develop over the endocardium indicate that tissue lesions can develop independently of vascular lesions. Degeneration, infarcts, necrosis, fibroses and hemorrhages may occur in various organs, depending on the location and specific characteristics of the vascular lesions. Ulcerative lesions of the gastrointestinal canal, nephritis, nephrosclerosis, fibrosis of the liver, nerve degeneration and cutaneous lesions may develop.

According to Grant's experience, the clinical onset of the disease is gradual. Malaise and rheumatic pains, with or without fever, may be the only symptomatic manifestations for a long time. Fever may be absent, low or septic. There may be considerable weakness and wasting. Skin lesions, if present, show much variation: simple erythema, erythema multiforme or nodosum, subcutaneous nodules, and pustular or necrotic lesions. Respiratory manifestations such as bronchitis, asthma, bronchopneumonia, pleurisy and infarcts are relatively often present. Tachycardia, congestive failure, nonbacterial endocarditis, pericarditis and angina are the usual cardiac signs. An unexplained and rather rapidly progressing hypertension has indicated the diagnosis in a few cases. In

about 80 per cent of the cases, albumin, hyaline and granular casts, a few red cells, gross hematuria and renal failure occur in various combinations. On rare occasions, Raynaud's syndrome, with or without subsequent gangrene, may occur. Digestive symptoms, such as vague abdominal discomfort, pain, constipation and diarrhea, are frequently present. At times, a so-called "acute abdomen" indicates surgical intervention. There may be blood or mucus in the stools. The ulnar, radial and anterior tibial nerves are particularly affected by the disease.

Ketron and Bernstein<sup>5</sup> studied the cutaneous manifestations of periarthritis nodosa. In their experience, the skin was affected in only about 25 per cent of the cases. The nodules appeared within the skin or subcutaneously, were usually not painful, and could disappear within several days. Erythemas, including scarlatiniform rashes, purpura and vesicular lesions were also present. If the larger cutaneous arteries were involved, the vascular lesion was usually typical, but lesions of the smaller arteries were often not characteristic.

The interrelation between asthma and periarthritis nodosa has been investigated in a selected group of cases by Rackemann and Green.<sup>6</sup> Of the 8 cases reported by them, all were women but 1. This is of interest because in the unselected groups the males predominate. Six patients developed asthma before the age of thirty-six years, and in most the course was short. In all the cases, the asthma was intrinsic in type. Four of the 8 patients had had trouble with the nose and sinuses. It is of particular interest that each of the 8 cases with asthma had an intense type of eosinophilia, in 3 reaching as high as 70 per cent of the white blood cells. The total white-cell count was also elevated, sometimes to 25,000 and in 1 case to 50,000. It should be pointed out, however, that this group was selected according to the observers' special interest in asthma. A study of the literature indicates that asthma does occur, but only in 10 per cent of the cases, and even when present is not always associated with eosinophilia.

Kernohan and Woltman<sup>7</sup> have studied the nervous system in 5 cases with periarthritis nodosa. In 3 cases, the peripheral nervous system was widely degenerated; in 1, the brain, and in 1, the choroid of the eye was involved. In only 1 case were the nutrient arteries to the peripheral nerves affected in the inflammatory process. The degeneration of the peripheral nerves appeared to be the result of occlusion or marked narrowing of the lumina of the nutrient arteries to the nerves. The degeneration, which was diffuse at lower levels, began as infarction at higher levels. No inflammation of the nerves was observed.

More recently, involvement of the central nervous system in periarteritis nodosa has been discussed in the German literature, but some of these publications have not been available. Stanojevic and Dimitrijevic<sup>8</sup> reported a case with involvement of the central as well as the peripheral nervous system. There were also changes in the eyegrounds designated as "neuroretinitis angiospastica," with early manifestations of retinal detachment. Since the patient also had hypertension, it is questionable whether these eyeground changes were specific. Judging from a study of the literature, I believe that these changes, if they do occur in periarteritis nodosa, usually depend on the associated hypertension. Rarely, however, as in the case reported with histologic findings by Gjertz, Nordl w and Svenmar,<sup>9</sup> the affection of the retina depended on typical lesions of the vessels. It is of interest that this patient also suffered from episcleritis.

Sawyer,<sup>10</sup> Allen<sup>11</sup> and Mondor, Ducroquet and Olivier<sup>12</sup> have reported on the surgical aspect of periarteritis nodosa. Occlusion or aneurysmal rupture of large or small arteries of various abdominal organs may lead to symptoms and signs imitating those of penetrating peptic ulcers, chronic cholecystitis, perinephritic abscess, pancreatitis, mesenteric infarction and peritonitis. Even the liver may be affected.

#### THROMBOANGIITIS OBLITERANS

Although this arteritis was described as "endarteritis obliterans" by von Winiwarter as early as 1879, and although it has been intensely studied since 1908 by Buerger and others, several significant aspects of the disease remain obscure. Not only is its etiology unknown, but the chronic stage of the disease is still confused with certain types of arteriosclerotic degeneration of arteries of the lower extremities. One needs particularly to know more of the early stage of the disease. It is surprising how few studies of biopsied specimens are available from this stage, when not only are the symptoms vague (paresthesias) but laboratory methods may even fail to demonstrate ischemia. In my experience, during the acute and the early stages, several characteristics of the disease may closely simulate those of periarteritis nodosa. At times, only the physiologic evidence of involvement of the larger arteries of the extremities may be the differential point.

In the recent literature, controversy about the etiology of thromboangiitis obliterans continues. It is probable that it can be caused by a number of factors, and frequently several of these factors seem to act synergistically. Recently, Good-

man<sup>13</sup> brought forward further evidence in favor of the rickettsial origin of the disease in at least one group. He claimed that thromboangiitis obliterans is a late manifestation of typhus fever. Gangrene as a direct complication of typhus fever has been reported repeatedly in the literature. Goodman also claimed that wherever typhus fever is endemic, there is a high incidence of thromboangiitis obliterans. In 100 cases of thromboangiitis obliterans studied by him, all patients gave a positive skin reaction following the intracutaneous injection of the rickettsia suspension. In 93 per cent of a corresponding number of control cases, this test was negative. In 100 cases of Brill's disease, it was 97 per cent positive. It is of interest in this connection that, in 1939, Parker<sup>14</sup> reported thromboangiitis obliterans as one of the complications of Rocky Mountain spotted fever and mentioned the frequency with which gangrene of the extremities was observed in animals inoculated with the rickettsia of this disease. Jordanus, as quoted by Goodman, described the sixteenth century epidemic of typhus that swept the Continent from Russia and caused millions of deaths. He mentioned as its chief features high fever, prostration and gangrene. Goodman also stated that in Japan "juvenile gangrene" is very common, and that rickettsial diseases, particularly tsutsugamushi, are likewise common. The vascular lesions in typhus fever, as described originally by Fraenkel,<sup>15</sup> consist of necrosis of the media of the small arteries within the cutaneous roseola, often associated with cellular reactions around the vessels. Fraenkel states that these vascular reactions remind one of those found in periarteritis nodosa, although the two diseases are not related to one another.

Arterial thrombosis of the extremities can occur, however, in a number of contagious diseases. Hoyne and Smollar<sup>16</sup> report the occurrence of gangrene of the lower extremities as a rare complication of scarlet fever. These writers were able to find in the literature 17 cases of such gangrene associated with scarlet fever. In 5 of these, the gangrene was bilateral, and in 16 it was so-called "dry gangrene." In 1 case reported by Hoyne and Smollar, there was an acute myositis above the area of gangrene, associated with panarteritis of most of the arterioles. In another, reported by Hoyne in 1915, dry gangrene of all four extremities developed, and in addition both ears and both cheeks were affected. It has been estimated that gangrene of the extremities occurs only once or twice in 30,000 cases of scarlet fever. This complication does not depend on the severity of the illness, but is considered as an unusual arterial response of the host.

In recent years, an increasing number of cases of thromboangiitis obliterans with central-nervous-system manifestations have been reported. These nervous symptoms may appear during either the acute or the chronic (arteriosclerotic) stage. Lindenberg<sup>17</sup> reports the affection of the central nervous system in this disease. He states that thromboangiitis obliterans is primarily a morphologic condition due to several agents. The effect on the central nervous system manifests itself in granular atrophy, with multiple small softened areas. In some cases, the distal small branches of the larger cerebral arteries are affected, whereas in others the vascular affection shows completely irregular involvement. Histologically, the lesions represent an endarteritis with thrombi. The media is relatively free. A perivascular inflammatory reaction may also be present. In chronic cases, the intima of the involved arteries is thickened. Recanalization of thrombosed arteries occurs frequently. The clinical manifestations are varied. Transient headaches, palsies, syncope and convulsions are prone to occur. The disease may imitate Alzheimer's disease.

The interrelation between thromboangiitis obliterans and the retinal vessels is of some interest. This topic has been discussed and reviewed recently by Wagener.<sup>18</sup> According to Wagener's report, Marchesani was impressed by the association, in a group of young persons, of recurrent hemorrhages into the retina and vitreous on the one hand, and transitory severe cyanosis of the extremities and trophic disturbances in the nails and skin on the other. In a number of these patients, there were no pulsations in one or more of the arteries of the lower extremities. All showed dilatation of the venous loops of the capillaries of the nailfolds, often associated with capillary hemorrhages. In the series of 22 patients reported by Marchesani, 2 suffered from gangrene of the toes, and 1 from gangrene of the fingers; 19 had evidence of "latent" Buerger's disease. In 1 case with gangrene, histologic examination revealed variable narrowing of the lumens of the smallest retinal vessels, which was due to swelling of the subendothelial tissues. In some of the larger arteries and veins, the endothelial layers were destroyed and the lumens filled with fibrinlike material. Other lumens contained material rich in cells. It is interesting that vessels of the iris and of the ciliary body were also involved. Marchesani suggested that these lesions of the vessels of the eyes were the ocular manifestations of Buerger's disease. Three of Marchesani's patients with primary symptoms of retinal periphlebitis showed atypical multiple sclerosis. Wagener states

that in the Mayo Clinic in a large series of patients with Buerger's disease he had but few cases of thrombosis of the retinal vessels. In 1 patient with presenting features of recurrent hemorrhages into the vitreous, typical manifestations of Buerger's disease developed years later. Other reports in the literature on the interrelation of eye symptoms associated with recurrent hemorrhages in the vitreous or vascular lesions in the retina on the one hand, and vascular affection of the extremities on the other, are summarized by Wagener. It is questionable whether in all these cases the ocular disturbances are manifestations of thromboangiitis obliterans, as originally suggested by Marchesani.

Since the chronic manifestations of thromboangiitis obliterans are adequately recognized, and since no outstanding contribution has been made recently to the knowledge of this phase of the disease, discussion of it will be omitted.

#### TEMPORAL ARTERITIS

Since the first case of temporal arteritis, reported in 1931, further cases of a similar nature continue to appear in the literature. Recently, Sprague and MacKenzie<sup>19</sup> have reported the case of a sixty-six-year-old man who complained of temporal neuralgia after a vague onset, and subsequently of temporomandibular arthralgia. The fact that in this patient, as has been true in other cases, the localized arteritis was associated with generalized debilitating conditions indicates that arteritis is a manifestation of a generalized disease. Bowers<sup>20</sup> summarizes the histologic findings in temporal arteritis. That the medial coat is usually affected is indicated by the presence of necrosis, at times with hemorrhage. The destroyed areas are replaced by granulated tissue in which giant cells are present. If all the coats are involved, there is intimal thickening and round-cell infiltration of the adventitia. The process may extend to tissues around the arteries. The lumens of the vessels may become closed. Both sexes are affected, and the patients are usually elderly, with signs of hypertension and arteriosclerosis. The cause of the disease is unknown, and its duration may range from five to six months, with some tendency to relapse, but with eventual complete recovery—in my experience, the duration has at times been but a few weeks. The cerebral, retinal and radial arteries can also be involved. In the case reported by Bowers, the occipital arteries were also affected.

Symptoms such as dull throbbing headaches, which become worse at night, fever, night sweats, poor appetite, loss of weight, anemia, weakness and mild leukocytosis may precede by several weeks

local signs of inflammation of the arteries. Small nodules may be felt over either the main branches or the smaller ones.

Recently, Hoyt, Perera and Kauvar<sup>21</sup> reported 3 cases of acute temporal arteritis from the Peter Bent Brigham Hospital. This brings the number of cases reported in the literature to over 20. They point out that in temporal arteritis the presenting symptom is usually a severe, boring headache referable to both sides of the head, often severer on one side than on the other. Often, too, the pain is more intense at night, and frequently neither morphine nor barbiturates succeed in abolishing the pain. The temporal regions and temporal arteries may be tender, and during the course of the illness the vessels may become enlarged, tortuous and surrounded by areas of hyperemia. Tenderness and painful mastication were prominent features in one of the cases reported. The severity of the illness is often entirely out of proportion to the degree of local disease present. These authors suggest that the inflammation of the temporal artery is perhaps but a local manifestation of a more widespread disease. The histologic findings on biopsied arteries in these cases were the same as those described above. It is interesting that from a practical standpoint the most effective treatment seems to be removal of a segment of the temporal artery. After such therapy, the headache is relieved, even though the fever and generalized symptoms may continue for weeks.

This local benefit from biopsy probably depends on section of the sympathetic nerves.

### CASE 27411

#### PRESENTATION OF CASE

A thirty-year-old single American woman was admitted to a mental hospital, where she remained until her death twenty years later.

The patient's family and personal histories were irrelevant. Her birth, infancy and early childhood were normal. She entered school at six and was considered very bright, but began to show a tendency toward seclusiveness and did not make friends easily. She enjoyed quiet, solitary diversions, was extremely sensitive, did not care for the company of men, and never had any love affairs. At the age of nineteen, the patient showed a definite change in her behavior: she cried a great deal, and was unable to give any reason for the change. At times she was hysterical, and could not control herself. This condition became progressively worse, and she began to lose interest in things she had previously liked. Finally, she would not talk at all. She then began to smile and laugh to herself, mumbled and spoke incoherently in low tones, and for several years would not converse. At the age of twenty-one, a panhysterectomy was performed on the recommendation of a psychiatrist. There was no further change in her general condition except that she gained about 100 pounds in weight. It was stated that until approximately one year before admission she was impulsive, violent and destructive. From the time of her institutionalization, when her physical and neurologic examinations were negative, until her death twenty years later, she showed progressive deterioration and reduction of activities. Eight years before death, the patient acted as if she had pain and tenderness in the gall-bladder region, and there were clay-colored stools. These symptoms persisted for a few weeks, then passed uneventfully. Two years later, the patient was placed on a diet and lost 85 pounds, the eventual weight being 165 pounds. Her condition was unchanged, and her general health appeared excellent. She was entirely out of communication with her physicians, mumbled to herself, fidgeted, and played with trinkets and toys. A Graham test showed no visualization of the gall bladder, but the examination was not

considered entirely satisfactory because of the large size of the patient and her general lack of co-operation. At this time, roentgenographic studies showed kidney outlines well visualized on both sides and normal in size, shape and position. Low in the pelvis on the left side, there were four small rounded areas of calcification, which had the appearance of phleboliths. Overlying the upper pole of the left kidney there was a group of irregular dense shadows, which could have represented renal calculi or calcified mesenteric lymph nodes. Repeat studies one year later again showed these several areas of density in the soft tissues, which were thought probably to represent calcified mesenteric nodes. No masses were felt on physical examination. The patient's condition remained approximately unchanged.

Eighteen months before death, the patient had, for the first time, an epileptiform convulsion accompanied by incontinence of urine and feces. The convulsion was generalized, and following it the patient seemed confused and drowsy. There were no definite neurologic findings, and no apparent headache, papilledema, stiff neck or localizing signs.

An electroencephalogram was suggestive of a pathologic process in the left occipitoparietal region. X-ray films of the skull were unusual but not definitely informative. There was irregular thickening of the inner table of the frontal bone, owing to hyperostosis, with unusually extensive calcification of the falx, but without evidence of chronic intracranial pressure.

Fifteen months before death, during the course of a routine physical examination done at the mental institution, an abdominal mass about 5 cm. in diameter was noted in the right lower quadrant. It was considered to coincide with the position of the calcified areas of density observed by x-ray study, and no further diagnostic procedures were attempted. On rectal examination, an extrinsic mass was felt about 5 cm. above the anus. Subsequent examinations showed several masses, about the same size, all palpable, and apparently increasing in size. Repeat stool examinations were negative for occult blood, the last test being done nine months before death.

The patient's condition continued with very little change until about six months before death, when she began to seem weak, and appeared to favor her abdomen as though there were pain or tenderness there. She vomited several times. There was no fever, and no constipation. The abdominal masses seemed somewhat larger. She failed gradually, showing physical deterioration. One month before death, she had "difficulty" with

respiration and developed a temperature of 102 to 104°F. Examination of the chest revealed dullness to flatness at the right base, with diminished breath sounds, and a roentgenogram taken with a portable machine showed evidence of fluid in the right pleural cavities and a linear band of density in the lung field, extending down from the right hilus.

The temperature from this time continued to fluctuate between 98.6 and 102.0°F., and physical findings in the chest increased; the patient be-

cannot remember ever to have heard of attempts to cure insanity by such an operation as this. It is very unfortunate that we do not know the details of the operation, since the term "panhysterectomy" has been applied to different operations at different times. As used today, it means that the uterus and tubes were removed and the ovaries were left behind. In 1910, I should suppose that it meant that the ovaries had also been removed. I think we can assume that the menses ceased, since we are given no information about

FIGURE 1. *Intravenous Pyelogram Showing Calcified Masses Superimposed on the Right Kidney Shadow.*

came weaker and developed mild dyspnea. She remained about the same for three weeks, and then quickly failed and died.

#### DIFFERENTIAL DIAGNOSIS

DR. JOE V. MEIGS: It would be presumptuous for a surgeon to attempt to discuss what kind of insanity this patient suffered from. It is evident even to the layman, however, that it was a major psychosis that demanded institutionalization. I

them. The insanity naturally made it impossible to inquire in detail about subjective symptoms such as periodic sensations in the breast and hot flashes, which would allow us to guess whether or not an artificial menopause was produced. It is obviously of great importance to know whether or not the ovaries were removed. I shall guess that they were, and am basing this assumption chiefly on the fact that the patient gained 160 pounds in a brief period after the operation. Of course, one can gain a great deal of weight after

any operation. One feels better and eats better, and the operation is an excuse for not exercising. However, a weight gain of 100 pounds is a striking phenomenon and definitely suggests that endocrine function was disturbed.

The gall bladder symptoms are reported to have persisted only a few weeks, they then passed uneventfully. This seems to me important because we are looking for all possible sites of primary neoplasm, to explain the subsequent history. But since the symptoms lasted only a few weeks, since we know that an unsatisfactory Graham test was later performed, and since the patient lived six years after the attack, I believe that there was nothing of serious consequence in the right upper quadrant. A report of an x-ray examination at this time suggested calcified mesenteric lymph nodes on the left side of the pelvis.

DR JAMES R. LINGLEY: This is the plain abdominal film taken six years before death. Low in the pelvis on the left, some small round areas of calcification, which at the time we thought were phleboliths, are visible. Higher up on the same side is a larger group of dense shadows that overlie the upper pole of the left kidney, these could be but probably are not renal calculi. They could be calcified mesenteric nodes. These films were taken six years later, and between the two examinations a remarkable change in the appearance of the abdomen had occurred. Unusually large areas of calcification were scattered throughout the abdomen. Here is one in the mid pelvis, which appears to form the upper border of a soft tissue mass. Another in the right upper quadrant has somewhat the appearance of a staghorn calculus. It lies outside the kidney outline, however, and above it (Fig 1). Here in the mid line is a large mass, which runs parallel to the transverse colon but was shown by a barium enema to be definitely outside the bowel. It was fairly movable, and we assumed that it was in the mesentery. In all these areas, the type of calcification is very unusual. It does not have the appearance of solid calcium but looks more as if the calcium were deposited in innumerable small particles throughout the soft tissue masses.

DR MEIGS: That was a great change—much greater than I had realized on reading the history. I note that they speak of a mass 5 cm in diameter, which was felt in the pelvis. That is only about the size of a golf ball, and if they could feel it in a patient who weighed 165 pounds it was probably even larger. The statement that repeated stool examinations were negative for blood is very important, and permits us to rule

out a primary tumor of the bowel. Evidently in the last few months the masses in the abdomen grew rapidly, and the patient began to go downhill, finally developing what might have been pneumonia, fluid in the chest or empyema. We are at a great disadvantage in not knowing certainly whether any ovarian tissue was left. If she still had her ovaries, one might think of a tumor primary in the upper abdomen, starting at about the time that she had the right upper quadrant difficulty, that metastasized to the ovaries and filled them with tumor analogous to a Krukenberg tumor. One also thinks of the possibility of a primary ovarian tumor, with metastases throughout the abdomen, including the omentum, this would account for the movable mid line tumor. Malignant ovarian tumors, particularly papillary adenocarcinomas, not infrequently undergo extensive calcification. Certainly that possibility cannot be ruled out. I have already committed myself, however, to the assumption that both the ovaries were taken out at the original operation. I do not know of any other neoplasms that calcify as extensively as this, and I must therefore fall back on the diagnosis of tuberculosis. I do not recall ever having seen a case of abdominal tuberculosis that progressed like this, but it remains my best guess and on that basis I assume that the final episode in the chest was probably a tuberculous pleurisy.

DR TRACY B. MALLORY: What would you say about the probability of tuberculosis, Dr Holmes?

DR GEORGE W. HOLMES: I am familiar with this case and consequently cannot give an unbiased opinion. I should like to point out that these are very unusual shadows. I cannot remember ever to have seen anything like this picture. Certainly it is not typical of tuberculosis.

DR WILLIAM RICHARDSON: I saw this patient two or three times and made a diagnosis of "rocks" in the abdomen of unknown etiology. The clinician who saw her placed most emphasis on the possibility of tuberculous etiology, but I think almost everyone was very much confused about the diagnosis.

#### CLINICAL DIAGNOSES

Schizophrenia  
Malignant disease, undetermined?  
Tuberculosis of retroperitoneal lymph nodes?

#### DR MEIGS'S DIAGNOSES

Tuberculosis of the abdominal lymph nodes  
Tuberculous pleurisy

## ANATOMICAL DIAGNOSES

Papillary cystadenocarcinoma of the ovary, with carcinosis of peritoneum and pleura and metastases to serous coats of intestines, liver, spleen and gall bladder.

Cardiac infarction.

Mural thrombus, right ventricle.

Pulmonary thrombus, left lower lobe.

Pulmonary infarct, left lower lobe.

Pulmonary atelectasis, bilateral, marked.

Hydrothorax, bilateral, marked.

(Schizophrenia.)

(Epilepsy.)

Frontal exostosis.

Ossification of falx cerebri.

Cholelithiasis.

Cortical cysts of kidney.

Hydronephrosis, left.

Hydroureter, left.

Operative scar: hysterectomy.

## PATHOLOGICAL DISCUSSION

DR. MALLORY: The autopsy proved one thing definitely—that it was not tuberculosis but metastatic tumor. All these tumor masses were extensively calcified. The calcification was mostly of a fine gritty character; gross examination suggested the type of calcification that is not infrequently seen in certain ovarian tumors and is due to very minute spherical masses of calcium known as psammoma bodies. When the microscopic sections came through, it was evident that the tumor was a papillary adenocarcinoma exactly similar in appearance to those that arise in the ovaries, with a great many psammoma bodies in it. It had metastasized very widely. We found many nodules scattered over the mesentery and on the bowels; apparently, these had started on the serosa and worked inward, some actually reaching the mucosa and almost obstructing the lumen. There were pleural metastases, which probably accounted for the chest fluid. The pelvis was totally filled with tumor material, and multiple sections at very close intervals failed to show anything that could be recognized as uterus, tubes or ovaries. If it were not for the story of the "panhysterectomy," I should assume that this was an ovarian tumor. We found no other probable primary site, and I have not happened to see a tumor of this type arising in any other tissue. Apparently, death was not due to the tumor but to a combination of a large infarct of the heart and pulmonary embolism. The skull showed extensive hyperostosis of the frontal bone, and the brain was grossly normal.

DR. MEIGS: I have seen ovarian tumors with calcification visible on x-ray films but never with as diffuse calcification as in these films. I should expect to see small granular areas more widely scattered.

DR. LINGLEY: We have seen another case with areas as close as these.

## CASE 27412

## PRESENTATION OF CASE

A sixty-two-year-old American schoolteacher was admitted complaining of marked breathlessness.

The patient had frequent sore throats until fourteen years before entry, at which time a tonsillectomy was performed. Subsequently, she had no recurrences. For about twenty-six years she had been slightly breathless on ordinary exertion, although this had not prevented her from carrying on her usual activities. For about five or ten years she had been aware of an irregularity of her heart, which had not been troublesome, however.

The irregularity had been constant so far as she knew. Four years before entry, she was seen by a physician because of bronchitis and was told that she had heart trouble and that her systolic blood pressure was 180. She was advised to take Digitora, one grain twice daily, which she continued to do until the time of entry. In spite of the treatment, the dyspnea had become more pronounced. Six months before admission, the patient consulted a physician for recurrent attacks of "intestinal flu," which were characterized by lower abdominal pain and nausea. The attacks were sufficiently severe to require rest in bed for a few days and sedatives for relief. They recurred at intervals for a few days to several weeks, but for the previous few months they had become less frequent and less severe. There was no associated vomiting, diarrhea or melena. Since the onset of this symptom, dyspnea had become more marked, and the ankles became swollen toward evening. For about four weeks, there were nocturnal attacks of dyspnea, associated with wheezing, which caused her to sit up in bed for relief. Occasionally, she was compelled to sleep in a sitting position. There was slight cough but no bloody sputum, and concomitant with the orthopnea there were a sensation of distress over the anterior chest and a tight feeling across the upper abdomen. For four days, there was marked swelling of the feet and legs up to the mid-thigh. There had been no previous attacks of rheumatic fever, chorea or related diseases.

Physical examination showed an elderly woman

propped up in bed, with slight cyanosis of the lips, face, fingers and hands. There was distention of the neck veins up to the angles of the jaw. A slight wheezing sound with respiration and occasional attacks of a Cheyne-Stokes type of breathing were noted. The apex impulse was diffuse and heaving, its maximal point being in the fourth interspace, 13 cm. to the left of the mid-sternal line. No thrills were palpable. The left border of dullness was 14 cm. from the mid-sternal line in the fourth interspace, 18 cm. in the third; the right border of dullness was 5 cm. in the fourth interspace. The rhythm was totally irregular, with an apical rate of 100. The pulse at the wrist was 60. The aortic second sound was moderately diminished, and the pulmonic was louder than the aortic and moderately accentuated. The first sound at the apex was marked by a moderate to loud, rather high-pitched systolic murmur, which was widely transmitted. At the apex, there was a short rumbling diastolic murmur immediately following the second sound. The blood pressure was 195 systolic, 110 diastolic. The radial arteries were soft, and the pulse moderately small in volume. Over the right lung base posteriorly, there were dullness and diminished to absent tactile fremitus. The breath sounds were diminished in intensity, but the voice sounds were of good quality. Throughout both lung bases, there were a moderate number of medium crepitant rales. The abdomen was soft, and the liver edge, which extended to the level of the umbilicus, was slightly tender. The spleen was not felt, and there was no evidence of ascites. There was edema of the lower extremities up to the mid-thigh.

The temperature was 100°F., and the respirations were 28.

Examination of the urine showed a specific gravity that varied between 1.008 and 1.014, with a slight trace of albumin. The sediment contained a rare red blood cell, 25 to 50 white blood cells and occasional granular casts per high-power field. The blood showed a red-cell count of 4,900,000 with a hemoglobin of 80 per cent, and a white-cell count of 10,000 with 73 per cent polymorphonuclears. A stool examination was negative. The blood Hinton reaction was negative. An electrocardiogram showed auricular fibrillation, with a tendency to right-axis deviation. There was low voltage and slurring of the QRS waves. T<sub>1</sub> was low; almost flat, and T<sub>2</sub> and T<sub>3</sub> low, with sagging ST intervals. Q<sub>4</sub> was 2 mm., and T<sub>4</sub> low and diphasic.

Three days after entry, shortly after a light lunch, the patient suddenly developed abdominal

discomfort and pain. This was relieved by a medicated enema, but shortly after its return, the patient became nauseated and vomited and her skin became ashen. She complained of epigastric discomfort and perspired freely. The blood pressure at that time was 200 systolic, 100 diastolic. There was an increase in moist rales in the chest, and the sputum was faintly tinged with bright-red blood. About fifteen minutes later, this attack subsided, but the patient continued to bring up streaked sputum for the next few days. Despite the administration of digitalis and sedatives, the patient's general condition remained unchanged, and the heart rate was not lessened. There was dyspnea at rest, and the cyanosis and engorgement of the neck veins continued. On the tenth hospital day, a right thoracentesis was performed, and 1360 cc. of straw-colored fluid withdrawn. This closed before the procedure was completed. Immediately after the tap, the patient stated that a constricting sensation, from which she had previously suffered, had subsided. Subsequently mercurial diuretics were administered, and the patient became more comfortable, although additional chest taps were necessary.

One month after entry, it was noted that nocturnal dyspnea was increasing in frequency and severity. Throughout this time, the temperature fluctuated between 98 and 101°F. Increasing dosage of digitalis failed to control the ventricular rate completely, and a pulse deficit of 40 to 80 continued. Blood-stained sputum was frequently noted. About ten weeks after entry, the patient was suddenly seized with a shaking chill and became markedly cyanotic, and the pulse at the wrist was imperceptible. She was more comfortable shortly afterward, although the temperature rose to 102°F. Three days later, note was made of pain across both sides of the upper abdomen, radiating to the back. The apical heart rate rose to 120, and there was an icteric tint to the scleras. At this time, the white-cell count was 30,000, with 89 per cent polymorphonuclears. The icteric index was 70. The nonprotein nitrogen of the blood was 38 mg. and the serum protein 4.4 gm. per 100 cc. Her condition remained essentially unchanged for the succeeding two weeks, and at that time copious spitting of blood began. This was associated with a slight cough, and the blood apparently welled up in the throat. The expectorated material was almost pure blood, with very little mucus. There was no dyspnea or jugular engorgement, but numerous moist rales were audible throughout both chests. Subsequently, her condition became progressively worse, and she died three months after entry.

## DIFFERENTIAL DIAGNOSIS

DR. EDWARD F. BLAND: Here is a woman who had been mildly incapacitated by shortness of breath, presumably referable to her heart, for twenty-six years, from the age of thirty-six to sixty-two, and with irregularity of the heart for the last ten years of her life. We know that it was fibrillation ultimately, and the terminal events consisted in congestive failure and certain complications thereof. I know of but one type of heart disease that is apt to permit such a long life with moderate disability for so many years—rheumatic heart disease. Irrespective of the physical signs, I think we can be reasonably certain of this on the basis of the history alone. From the physical signs described, the patient undoubtedly had extensive involvement of the mitral valve, with regurgitation and stenosis. There was, of course, marked enlargement of the heart. Most of the other signs described are consistent with rheumatic heart disease and heart failure. I suppose that an x-ray film was taken. She could hardly have been in the hospital for three months, with all these things happening, without a chest film. I should be interested in that.

DR. BENJAMIN CASTLEMAN: No x-ray films were taken.

DR. BLAND: Perhaps the patient was too sick. It would have been of interest to search for calcification of the mitral valve. There probably was some, but it might have shown up only under the fluoroscope, or perhaps not even there. It would have been of further interest to know if we were dealing with something other than cardiac impairment as a contributing cause of the long-standing dyspnea.

The electrocardiogram is of some interest. It shows a little right-axis deviation; I should have expected more. Of course, this patient also had hypertension, which imposed an added strain on her heart, principally on the left ventricle, and hence would tend to lessen the degree of right-axis deviation that she might otherwise have had. The description in the record covers satisfactorily the other electrocardiograms shown here on the screen. There was auricular fibrillation, rather low voltage and very slight right-axis deviation, the degree of which, as noted above, is a little disturbing. There was also a digitalis effect on the T waves, although, as we shall note shortly, the ventricular rate was controlled only with a good deal of trouble.

I should like to speculate a little about the probability of slight scarring of the aortic valve in the presence of such extensive rheumatic involvement of the heart. Nothing in the physical signs de-

scribed permits one to guess that such scarring occurred, but I think that there is perhaps a fifty-fifty chance of finding a relatively slight degree of aortic-valve involvement.

Certain features of the final illness require some special consideration, and I think there may be some reasonable difference of opinion concerning them. The attacks, called abdominal, before she came to the hospital interest me. They coincided with the beginning of frank congestive failure and consisted in pain and nausea, without other gastrointestinal symptoms. We know that pain in the abdomen with congestive failure is common and most frequently due to demonstrable engorgement of the liver. Sometimes, people have pain from a sore liver oftener at night than during the day, probably because of the semirecumbent position assumed in bed, whereas when they sit in a chair the liver is not quite so encroached on. For a number of years, we have been searching without success for an explanation of the abdominal pain when congestive failure is not evident in patients with well-marked mitral stenosis. Here we need, I think, look no farther than to the congestion of the liver and of the gastrointestinal tract as a satisfactory explanation. Mesenteric embolism seems unlikely.

We now come to a second point, which I think needs a little discussion. These recurring episodes of pulmonary distress, which were associated with an increase in the signs of congestion and one of which was accompanied by an actual chill, together with the vague pain in the chest followed by fever, hemoptysis and icterus, were certainly due to multiple pulmonary infarction. This patient had two very good reasons for having both respiratory distress and hemoptysis. She had obvious congestion of the lungs, and she might have had a little blood in the sputum simply from this. However, these recurring episodes, especially the one followed by icterus, indicate multiple pulmonary infarcts. The degree of icterus in this patient is interesting, for an icteric index of 70 represents considerable jaundice and hence extensive infarction, I should guess. Someone asked me recently if we saw icterus as a result of infarction of organs other than the lungs. At the time, I did not recall such a case.

DR. CASTLEMAN: We have had one case of jaundice associated with infarction of the heart without pulmonary infarction. It was reported several years ago.<sup>1</sup>

DR. PAUL D. WHITE: Yes; I remember that case. I suppose that such a case is related to the extent of hemolysis and the passive congestion in the liver.

DR CASTLEMAN Yes, both factors must be present

DR BLAND The next point I should like to comment on is this patient's fever. There are several adequate reasons why she may have had fever. Extensive congestive failure may give rise to a degree or two. We know that the pulmonary infarcts could have caused fever, but the question is raised whether any other infection was present, bacterial or otherwise. Perhaps not, but I shall keep that possibility in mind for a final word later.

Toward the end of her life, the patient had a low serum protein, 4.4 gm per 100 cc, which is within the edema range. She had several obvious causes for a low serum protein. Undoubtedly, the dietary intake for one reason or another had been inadequate. She had congestion of the liver and had lost fluid by both diuresis and tapping. All these factors might have contributed. Then we come to the question of some obscure infection in the heart as a possible added factor in her demise. In a young person, heart failure complicating a rheumatic heart is a fairly reliable sign of underlying infection of some sort or other, but this patient was too old to apply this general principle without other supporting evidence, so that we have to discount the presence of congestive failure as a possible indication of active infection, bacterial or rheumatic. A good deal of difficulty was obviously encountered in controlling the ventricular rate. Among the things in general that make it difficult to control the ventricular rate when fibrillation is present are infection, infarction in the lung and thyrotoxicosis. There is no reason to suspect thyrotoxicosis. I think that the patient had multiple infarction of the lungs which is probably the best explanation.

A final word about the lungs. I was puzzled why the patient bled so much from her lungs at the end, since there was not much evidence at that time of gross congestion and since, in fact, the pulmonary congestion seemed temporarily better, yet she raised almost pure blood, without sputum and with very little cough. That is a little unusual, but perhaps the pulmonary circulation was better because she was raising blood. We know that patients with rheumatic heart disease and mitral stenosis are prone to bleed from the lungs from either infarction or congestion and at times without clinical evidence of either. I think it unlikely that Dr. Castleman will tell us later that the patient had a rheumatic pneumonitis. Although I do not like to discard it without some further comment, I do not believe I could make a diagnosis of acute rheumatic fever.

Did she have bacterial endocarditis? I do not believe so for several reasons. She had auricular fibrillation. That does not exclude endocarditis, but the combination is a little unusual. She had chronic congestive failure for at least nine months. That would be most unusual if the heart failure were due to bacterial infection. Did she have some chronic disease of the lung to explain her respiratory symptoms rather than chronic heart disease? Probably not. She had respiratory symptoms for too many years, with no clubbing of the fingers and no suggestive sputum during that time.

In summary, I should say that in spite of the patient's age she had chronic rheumatic heart disease, with extensive mitral involvement, both stenosis and regurgitation. She had a complicating hypertension, which may have been an added factor in the later downhill course and ultimate death, but the rheumatic disease of the heart was, I believe, of first importance. She died of chronic congestive heart failure, with recurring pulmonary emboli and infarction.

DR HOWARD B. SPRAGUE Abdominal pain in these patients with cardiac failure bothers me as much as it does Dr. Bland. Some of them who do not have much enlargement of the liver may have acute engorgement causing pain. Also, we have been surprised to find renal infarcts in these patients. I want to ask Dr. Castleman, Is it possible to get small enough emboli to the blood supply of the intestines to have attacks of pain without infarction of the intestinal wall?

DR CASTLEMAN I do not believe so. Infarction is found only when the larger vessels are occluded, because ordinarily there is enough collateral circulation between the intestinal branches to prevent it. I suppose emboli in the mesenteric branches are not uncommon, but I do not believe they have been hunted for seriously enough.

DR WHITE With reference to renal infarction, Dr. Reno R. Porter and I<sup>2</sup> found that renal infarcts are usually painless. The majority of patients whom I have seen with abdominal pain complicating heart failure have had distention of the intestine from gas due, in part at least, to stasis. They usually have liver engorgement also, but not always. Of course there is some thing here besides <sub>3, 15</sub>

#### CLINICAL DIAGNOSES

Valvular disease, chronic, cardiac  
Mitral stenosis  
Hypertension  
Pulmonary infarction

## DR. BLAND'S DIAGNOSES

Rheumatic heart disease.  
Mitral stenosis and regurgitation.  
Auricular fibrillation.  
Congestive heart failure.  
Multiple pulmonary infarcts.  
Hypertension.

## ANATOMICAL DIAGNOSES

Rheumatic heart disease, chronic, with mitral stenosis.  
Cardiac hypertrophy.  
Mural thrombus, left auricle.  
Thrombosis of popliteal vein, left.  
Pulmonary embolism, bilateral.  
Pulmonary infarction, right lower lobe.  
Icterus.  
Renal infarction, multiple, bilateral, healed.  
Arteriosclerosis, marked aortic, moderate coronary.  
Nephritis, chronic vascular, marked.  
Chronic passive congestion of liver and spleen.  
Pulmonary congestion.  
Hydrothorax, bilateral.  
Peripheral edema.  
Peritonitis, chronic fibrous.  
Cholelithiasis.  
Dilatation of bile ducts.  
Focal necrosis and abscess formation of pancreas.

## PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: This patient had a large heart, weighing 800 gm., with marked dilatation and hypertrophy of the right auricle and ventricle. The right ventricle measured 5 mm. in thickness, which I think would be enough to cause right-axis deviation.

DR. BLAND: It is not entirely a question of the thickness. It is a question of disproportion between the normal ratios of the two ventricles.

DR. CASTLEMAN: The left measured 17 mm. The mitral valve was markedly stenotic and calcified, although the opening measured 3 cm. in circumference. In the left auricular appendage was a mural thrombus, and there were small healed renal infarcts that may have had something to do with the pain, but I doubt it. There were several large infarcts in the lower lobe of the

right lung involving about two thirds of the lobe; the other lobes were normal. The extent of the infarction, together with the congestion of the liver, certainly accounts for the icterus. There was about 200 cc. of fluid in the right pleural cavity, and 50 cc. in the left. In addition, old adhesions were found all over the abdomen, especially in the region of the gall bladder, which was filled with two large stones and inspissated bile. The pancreas showed several areas of acute fat necrosis, and I believe the abdominal pain was due to some disturbance in the biliary tract associated with chronic pancreatitis. Small foci of old fat necrosis are occasionally seen without symptoms, but here it was much more acute than usual.

DR. WHITE: Was there any active myocardial rheumatic disease?

DR. CASTLEMAN: No; we were unable to find any evidence of active rheumatic infection.

DR. BLAND: The aortic valve was not involved?

DR. CASTLEMAN: It showed a little calcification on the sinus side of the valve but no true inter-adherence. I think one would question whether there was any.

DR. BLAND: Was there any pericarditis?

DR. CASTLEMAN: No.

DR. SYLVESTER MCGINN: How about the leg veins?

DR. CASTLEMAN: The source of the infarct in the lung was the left popliteal vein. It is often supposed that the infarcts in the lungs in patients with fibrillation are due to mural thrombi in the right auricle, but if one examines the deep leg veins in those cases, another more likely source may be uncovered. In this case, the right auricle was normal.

## Erratum

In Case 27331 of the "Case Records of the Massachusetts General Hospital" in the August 14 issue of the *Journal* (line 18, column 1, page 272), the word "aminophyllin" was used erroneously for aminopyrine. The speaker did not mean to imply that aminopyrine caused liver damage, but that it was an equally dangerous drug, the toxicity in this case being directed toward the granulocytes.

## PUBLIC EDUCATION IN MEDICAL MATTERS

THE Diabetes Education Program that is being sponsored by the Metropolitan Life Insurance Company is an encouraging example of public interest in good medicine. The increasing evidence that the early recognition and careful control of diabetes are important in checking the progress of the pancreatic and neurovascular lesions makes such a program particularly timely.

The economic value of good health to such an insurance company is of course obvious. But good public health or that of the individual is of equal value to private enterprise. Loss of work due to ill health is an economic burden to almost all industry. The vast sums of money spent annually

by the American people on life and sickness insurance provide evidence concerning the value that they have long placed on life and health. Advances in medical science have so increased the effectiveness of available medicine that the public's interest is shifting from *insuring* health and life by cash indemnities to *securing* health and longevity by medical care. The expansion of health programs by state departments of public health and a variety of nonprofit lay organizations reflects the public's increasing appreciation of the effectiveness of modern medicine. The National Health Conference and the recent National Nutrition Conference were reflections of public awareness and interest. The federal government has responded through the programs of the United States Public Health Service, of the Maternity and Child Welfare Division of the Department of Labor, and of the National Health Institute at Bethesda, Maryland. This increased awareness is creating an increased demand for medical care. To finance this care, a variety of plans for voluntarily distributing and budgeting the costs of medical care are developing throughout the country. Although it is not widespread, there is even some demand for compulsory health insurance. Insofar as the layman's medical education is good and the plans for budgeted health services are sound, the medical profession, as well as the public, will benefit. The result should be more and better medicine more widely and, therefore, with present economic trends, better paid for in the long run.

So far so good, and the medical profession should indeed be happy. But there are, of course, many who will turn the public's interest in medicine to their personal advantage. For every educational program like that sponsored by the Metropolitan Life Insurance Company for better health, there will be one hundred programs on the radio and in the press sponsored by commercial organizations for the sale of unneeded or worthless medication. The same American advertising genius that has popularized alkalinizing, laxativizing and antihaltizing remedies apparently is taking over the newly cultivated fields of vitamin and hormone

therapy. As it does so, the money that the public should spend for effective health and medical services will be squandered to such an extent that sums spent on the trial-and-error method of establishing workable insurance schemes will seem inconsequential. But no matter what becomes of the money, the medical profession in the end will pay the bill, so the public will be happy anyway.

## MEDICAL PATENTS

THE medical profession has always been imbued with the idea of the free exchange of knowledge gained from research. The meetings of our societies and the contents of our journals bear witness to this fact. The inauguration of medical patents in certain fields has cast a blight on this traditional ideal. Holders of medical patents are learning that the onerous duties of controlling and protecting their patents tend to cast disturbing shadows over the glory of discovery.

The Department of Justice recently chose to bring suit against three leading pharmaceutical manufacturers in the United States on the charge of fixing the price of insulin in violation of the Sherman Act. Heavy fines were imposed. The University of Toronto, holders of the patent, had granted licenses to these manufacturers to make and sell insulin. The Insulin Committee of this institution has apparently carried out its responsibilities concerning standards and prices of the product marketed in a manner satisfactory to the medical profession of North America, and this committee has never ventured to control research in the field of diabetes. The judgment, then, seems to be against the manner of price fixing rather than against the quality of the product or any unreasonable profit on the part of the manufacturers.

The emoluments received by the patentees in this case were beyond the scope of this judgment. At one time, the royalties on insulin were 10 per cent, whereas those on the Dick patent, held by a committee associated with the University of Chicago, were 5 per cent. Yet, on June 4, 1935, the Council of the Massachusetts Medical Society

adopted a resolution expressing disapproval of the Dick patent, the objection being based purely on the ground of the patentees' monopolistic control of investigative work in the field of scarlet fever.

Since patents appear to be necessary for the control of standardization of products in the existing situation, the control should lie with the highest tribunal of our medical councils or with the Government. The patents would then be dedicated to the public, and all royalties abolished in conformity with a tradition handed down from the days of Hippocrates. This suggestion was presented more than a year ago before the House of Delegates of the American Medical Association, but was set aside. It behooves the American Medical Association to renew its interest in the solution of this problem before federal authorities, probing farther into medical patents, charge organized medicine with lending support to a monopolistic practice that strikes at the very heart of academic freedom.

---

## MEDICAL EPONYM

### Koch's POSTULATES

These postulates are laid down in the monumental contribution of Robert Koch (1843-1910), "Die Aetiologie der Tuberculose (The Etiology of Tuberculosis)," which was delivered as a lecture to the Physiological Society in Berlin on March 24, 1882. It appears in the *Berliner klinische Wochenschrift* (19: 221-230, 1882). A portion of the translation follows:

To prove that tuberculosis is a parasitic disease occasioned by the invasion of the bacilli and primarily caused by their growth and increase, these bacilli had to be isolated from the body, and kept in pure culture until they were free from any possible contamination with other disease products of the animal organism; and finally it was necessary to reproduce the same disease picture of tuberculosis (which experience showed could be obtained by injection of naturally produced tuberculous material) by transfer of the isolated bacilli into animals.

Koch then described his method of staining the tubercle bacilli, finding them in the lesions and culturing them. His success in reproducing tuberculous lesions and recovering the bacilli from them established a standard for this type of bacterial investigation that has remained fixed ever since.

R. W. B.

## MASSACHUSETTS MEDICAL SOCIETY

SECTION OF OBSTETRICS  
AND GYNECOLOGY\*ALBUMINURIA AND HYPERTENSION FOLLOWED  
BY POST PARTUM ECLAMPSIA AND DEATH

A thirty-one year-old para III was seen in the fifth month of pregnancy for the first time. Following that, she was seen by the district nurse quite frequently.

The past history was not remarkable. Physical examination at the time of her visit to the physician was reported to have been negative.

Six weeks before delivery, the patient had a systolic blood pressure of 150. During the next month, she was seen ten times by the district nurse, who found that the systolic blood pressure averaged from 150 to 200 and that there was a trace of albumin in the urine. The attending physician was notified of these findings. The patient started in spontaneous labor at term and delivered herself of a living child. An hour later, several severe convulsions occurred. The patient was sent to the hospital and died approximately one day after delivery, without regaining consciousness.

*Comment.* Albuminuria and increased blood pressure during pregnancy, and convulsions following delivery, still occur in this day of enlightened medicine. There is no reason to suppose that this death was unavoidable. Any conscientious practitioner, when notified that a patient had a systolic blood pressure of 200 and a trace of albumin a few weeks before the expected date of delivery, would have done something about the situation. Such a patient should be hospitalized and intensively treated by a milk diet and milk of magnesia, salt should be omitted from the diet. If the blood pressure does not come down, labor should be induced, thus preventing a fatality. This case is a disgrace to the medical profession.

\*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters should be addressed to Dr. Raymond S. Tuttle, Secretary, 230 Dartmouth Street, Boston.

## APPLICANTS FOR FELLOWSHIP†

PUBLISHED IN ACCORDANCE WITH THE PROVISIONS OF THE BY LAWS (CHAPTER V, SECTION 2) AS AMENDED MAY 22, 1941.

## BARNSTABLE DISTRICT

ROBINSON, JOSEPH, 25 Barnstable Road, Hyannis  
Middlesex University School of Medicine, 1933 Sponsor  
Frank Travers, Kings Highway, Barnstable.

Some of these applications were received too late under the By Laws of the Massachusetts Medical Society to be considered at the annual examination on December 1.

SANBORN, FREDERICK, Barnstable County Sanatorium, Pocasset.

Harvard Medical School, 1937.

SOBEL, HARRY, 55 Winter Street, Hyannis  
Middlesex University School of Medicine, 1932 Sponsor  
Harold F. Rowley, Harwich Port.

TRIPP, EDWIN P., JR., Falmouth.  
Jefferson Medical College of Philadelphia, 1938.

Donald E. Higgins, Secretary  
Main Street, Cotuit.

## BERKSHIRE DISTRICT

CARPENTER, FREDERICK J., 199 Springside Avenue, Pittsfield.

McGill University Faculty of Medicine, 1936.

MCALPIN, KENNETH R., 29 Hoxsey Street, Williamstown.  
Columbia University College of Physicians and Surgeons, 1910.

George S. Reynolds, Secretary  
7 North Street, Pittsfield.

## BRISTOL NORTH DISTRICT

BEDINGER, ADA D., Taunton State Hospital, Taunton.  
University of Pennsylvania School of Medicine, 1939.

BELMONT, FRED R., 42 Summer Street, Taunton.  
University of Berlin, 1921 Sponsor William H. Swift, 141 High Street, Taunton.

BOYD, JAMES G., Taunton State Hospital, Taunton.  
Boston University School of Medicine, 1939.

HAMEL, ALBERT G., Taunton State Hospital, Taunton.  
Georgetown University School of Medicine, 1929.

William H. Swift, Secretary  
141 High Street, Taunton.

## BRISTOL SOUTH DISTRICT

BERNSTEIN, SIGMUND, 415 County Street, New Bedford.  
University of Vienna, 1909 Sponsor Charles A. Bonney, Jr., 41 Maple Street, New Bedford.

HAGIN, CORNELIUS E., JR., 229 Belmont Street, Fall River.  
Medical College of Virginia, 1935.

MAGNOLSON, PAUL L., 76 Cottage Street, New Bedford.  
New York University College of Medicine, 1937.

MOONEY, DANIEL L., 164 Colfax Street, Fall River.  
Harvard Medical School, 1937.

PICARD, JULIUS, 473 Walnut Street, Fall River.  
University of Heidelberg, 1921 Sponsor Samuel Brown, 130 Rock Street, Fall River.

SCHWARTZ, WILLIAM, 240 Second Street, Fall River.  
College of Physicians and Surgeons, Boston, 1934 Sponsor Thomas G. Clarke, 181 Purchase Street, Fall River.

SMITH, VERA L., Swansea.  
College of Medical Evangelists, 1937.

Albert H. Sterns, Secretary  
31 Seventh Street, New Bedford.

## ESSEX NORTH DISTRICT

KAPLAN, LOUIS S., Birch Road, Salisbury.  
Middlesex University School of Medicine, 1935 Sponsor Clarence R. Hines, 39 Market Street, Amesbury.

SCHLOMER, GEORGE M., Georgetown.

University of Munich, 1910. Sponsor: Harry C. Solomon, 270 Commonwealth Avenue, Boston.

#### DEATHS

POWERS — GEORGE H. POWERS, M.D., of Boston, died October 4. He was in his sixty-fifth year.

Born in San Francisco, Dr. Powers received his degree from the University of California Medical School in 1902. He was a fellow of the Massachusetts Medical Society and the American Medical Association, and was a member of the American Board of Otolaryngology and the American Otological Society.

He is survived by his widow and two daughters.

ROGERS — MARK H. ROGERS, M.D., of Boston, died October 5. He was in his sixty-fifth year.

Born in South Sudbury, Dr. Rogers graduated from Williams College in 1900 and received his degree from Harvard Medical School in 1904. He was professor of orthopedic surgery at Tufts College Medical School, chief

of the orthopedic service at the Beth Israel Hospital and orthopedic surgeon at the New England Deaconess Hospital. He was a fellow of the Massachusetts Medical Society, the American Medical Association and the American College of Surgeons.

His widow, a daughter, a son and two grandchildren survive him.

## BOOK REVIEWS

*Papers of Walter Hampton Frost, M.D. A contribution to epidemiological method.* Edited by Kenneth F. Maxcy, M.D. 8", cloth, 628 pp. New York: The Commonwealth Fund, 1941. \$3.00.

Frost, at the time of his death in 1938, was one of the leading epidemiologists in America. Brought up in the United States Public Health Service, a ground school for practically every important epidemiologist developed in this country, he was later chosen by William H. Welch to serve in the new School of Hygiene and Public Health established in 1919 at Johns Hopkins University. His previous work, particularly his accepted studies of acute antenatal poliomyelitis in Iowa, Ohio and New York, which were considered among the outstanding reports on the disease in this country, and his other studies on typhoid fever, sewage pollution and influenza had given him a worldwide reputation. After becoming established at Johns Hopkins, he showed great interest in tuberculosis, partly no doubt, because he suffered from this disease himself, and papers on this subject, in addition to the contributions on the principles of public health practice formed the bulk of his work during the latter years of his life. As these papers were widely scattered in medical periodicals, a committee of some of his friends and associates was formed in 1938, with Dr. K. F. Maxcy and others, to publish them in book form. The project had the sympathetic support of the Commonwealth Fund and a volume of over 600 pages is now available. The papers in general have been kept in their original form although most of the charts have been redrawn for uniformity. Dr. Maxcy has written a brief but stimulating introduction giving the chief facts about the life of Frost and an estimation of his scientific contributions and character. The frontispiece is an excellent reproduction of a photograph of Frost, and the whole volume is superbly printed. Rarely does one meet in medical publications such a satisfactory and fitting format. The frame, indeed complements the picture and the picture itself is of one of America's great epidemiologists. The world of medical literature has been enriched by the devotion of Dr. Maxcy to his predecessor and the farsightedness of the Commonwealth Fund in seeing that this book was published.

*Infantile Paralysis. Interior poliomyelitis.* By Philip Lewin, M.D. 8", cloth, 372 pp., with 165 illustrations. Philadelphia: W. B. Saunders Company, 1941. \$6.00.

This book is a careful review of all aspects of poliomyelitis with particular emphasis on orthopedic after care. Written by an orthopedic surgeon of note, this important aspect of the treatment of poliomyelitis receives adequate attention, with numerous illustrations of operative procedures. In the earlier chapters, however, on etiology, portals of entry, resistance and immunity, epidemiology and similar topics, as well as in those on examination and diagnosis, these points do not appear to be adequately covered. The ideas are sound, and the statements accurate in general although some may disagree with the

opinion expressed in the chapter on diagnosis. The book can nevertheless be highly recommended as an excellent brief account of a disease that is ever present and is a constant menace. This is a practical book of particular value to orthopedic surgeons and to the general practitioners who wish to understand the mechanics of orthopedic appliances and surgical procedures.

*Modern Drugs in General Practice.* By Ethel Browning, M.D., Ch.B. 8", cloth, 236 pp. Baltimore: Williams and Wilkins Company, 1940. \$3.00.

This is a list of drugs in common use, with a brief bibliography attached to each chapter. In most cases, the name of the drug, as supplied in Great Britain, is added, since the book emanates from British sources. It is a valuable, up-to-date listing of current pharmaceuticals, briefly presented, giving details about the drugs themselves, their clinical indications, dosage, toxic effects, the mode of action and the results of treatment. The book should prove to be of some value to American physicians, but other books of equal value, written from the American standpoint, are available.

## NOTICES

### ANNOUNCEMENT

DR. FRANK R. STENZEL announces the removal of his office from 1580 Beacon Street, to 1801 Beacon Street, Waban.

### SOUTH END MEDICAL CLUB

A meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, October 21, at 12 m. Dr. Donald E. Currier, chief of the Medical Division of the Massachusetts Selective Service System, will speak on "The Physician in National Defense."

Physicians are cordially invited to attend.

### JOHN T. BOTTOMLEY SOCIETY

The fourth annual clinical meeting of the John T. Bottomley Society will be held at the Carney Hospital on Wednesday, October 22, at 10:00 a.m. Luncheon will be served at 1:00 p.m. The annual dinner will be held at the Copley Plaza at 6:30 p.m.

#### PROGRAM

Erythroblastosis Fetalis Dr. William C. Moloney  
Recent Advances in the Treatment of the Menopause.  
Dr. John J. Thornton.  
The Management of the Acute Gall Bladder Dr. William J. Sullivan  
Common External Diseases of the Eye Dr. George R. Gagliardi  
Recent Advances in the Treatment of Skin Diseases  
Dr. John T. Foley

### NEW ENGLAND PATHOLOGICAL SOCIETY

A meeting of the New England Pathological Society will be held at the Boston Lying-in Hospital on Thursday, October 16, at 9 p.m.

#### PROGRAM

Morphologic Findings in Endometrial Biopsies from 100 Cases of Bleeding during the First Trimester of Pregnancy and from 34 Postabortal and Normal Puerperal Uteri. Dr. Robert N. Rutherford

Bilateral Cortical Necrosis of the Kidney: A report of 2 cases, with some observations on the pathogenesis and evolution of the renal lesion. Dr. Walter H. Sheldon.

The Relation of Ovarian Stromal Hyperplasia and Thecoma of the Ovary to Endometrial Carcinoma. Dr. Lent C. Johnson.

Observations on a Series of Early Normal and Abnormal Human Ova Obtained Prior to the First Missed Menstrual Period. Dr. A. T. Hertug.

Business meeting.

Collation.

## NEW ENGLAND SOCIETY OF PSYCHIATRY

The regular fall meeting of the New England Society of Psychiatry will be held at the Augusta State Hospital, Augusta, Maine, on Friday, October 17. Dr. Donald E. Currier, chief of the Medical Division, Massachusetts Selective Service System, will speak on "Medical and Psychiatric Features of the Selective Service Program."

## AMERICAN CONGRESS ON OBSTETRICS AND GYNECOLOGY

The second American Congress on Obstetrics and Gynecology will be held in St. Louis, Missouri, April 6 to 10, 1942. All the meetings and the commercial, educational and scientific exhibits will be held in the Public Auditorium.

The general plan for the program will be much the same as that of the first congress, which was held in Cleveland in 1939, with sectional meetings for the various groups (nurses, public-health officers, administrators, educators and physicians), general sessions for all members attending the congress and round-table discussions. The evening sessions will be open to the general public.

Admission to the congress will be by membership cards only, which may now be secured by the payment of a \$5.00 registration fee. All mail should be addressed to and further information may be obtained from the American Congress on Obstetrics and Gynecology, 650 Rush Street, Chicago.

## UNITED STATES CIVIL SERVICE EXAMINATION

### Maternal and Child-Health Specialists

Employment registers are to be established by the Civil Service Commission to fill maternal and child-health specialist positions in the Children's Bureau of the Department of Labor. Vacancies in similar positions in state agencies co-operating with the Children's Bureau may also be filled from these registers at the request of the states concerned. The examination announcement just issued by the Civil Service Commission to recruit persons for these positions allows the filing of applications until November 15.

There are three options in which persons may qualify: pediatrics, obstetrics and orthopedics. For each of these, employment lists will be established for administrative, research and clinical positions. The duties of the administrative positions include giving consultations and advisory service to state and other governmental agencies carrying out maternal and child-health programs. The research positions involve the planning or directing of studies in such fields as infant and maternal mortality, and child growth in relation to social, economic and other factors. Persons appointed to clinical positions will do clinical work in one of the options.

A written test will not be given for these positions. Competitors will be rated on their education, experience and corroborative evidence. Applicants must have graduated from a medical school of recognized standing and must have served a one-year internship. In addition, they must have had full-time postinternship clinical training, as well as other appropriate experience in the option selected and in the type of work in which they seek appointment.

Physicians who are interested in this opportunity are urged to seek further information about these positions, which pay from \$3200 to \$5600 a year. Further information and application forms may be obtained from the commission's representative at any first-class or second-class post office or from the central office in Washington, D. C.

## SOCIETY MEETINGS AND CONFERENCES

### CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, OCTOBER 12

#### MONDAY, OCTOBER 13

12 15-1 15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital amphitheater.

#### TUESDAY, OCTOBER 14

\*9-10 a.m. Medical clinic. Dr. S. J. Thannhauser. Joseph H Pratt Diagnostic Hospital.

12 15-1 15 p.m. Clinicoradiological conference. Peter Bent Brigham Hospital amphitheater.

8 15 p.m. Harvard Medical Society. Peter Bent Brigham Hospital amphitheater.

#### WEDNESDAY, OCTOBER 15

\*9-10 a.m. A Dental Pediatric Presentation. Dr. F. C. McDonald and Dr. Leonard Despres. Joseph H. Pratt Diagnostic Hospital.

\*12 m. Clinicopathological conference. Children's Hospital.

#### THURSDAY, OCTOBER 16

\*8 30 a.m. Combined clinic of the medical, surgical, orthopedic and pediatric services of the Children's Hospital and the Peter Bent Brigham Hospital, at the Children's Hospital.

\*9-10 a.m. Medical clinic. Dr. S. J. Thannhauser. Joseph H Pratt Diagnostic Hospital.

8 p.m. New England Pathological Society. Boston Lying in Hospital.

#### FRIDAY, OCTOBER 17

\*9-10 a.m. Gastric Ulcer. Dr. Sara Jordan. Joseph H Pratt Diagnostic Hospital.

#### SATURDAY, OCTOBER 18

\*9-10 a.m. Presentation, with discussion, dispensary and district cases. Joseph H Pratt Diagnostic Hospital.

NUMBER 16

## SOME USES AND ABUSES OF CHEMOTHERAPY IN PNEUMONIA\*

MANWELL FINLAND, MD,† OSIER L. PETERSON, MD,‡ AND  
ELIAS STRAUSS, MD,‡

BOSTON

THERE can now be little doubt concerning the value of the newer sulfonamide drugs in the therapy of pneumonia. Almost every physician has had some personal experience to demonstrate the effectiveness of sulfapyridine or sulfathiazole in this disease. There are, however, a number of important practical problems that require elucidation on the basis of recent accumulated experience. In this paper, we present our views on some of these problems.

### GENERAL CONSIDERATIONS

*Choice of sulfonamide drugs in the treatment of pneumonia.* The three compounds that have proved effective and have been used widely in the treatment of bacterial infections are sulfanilamide, sulfapyridine and sulfathiazole; a fourth drug, sulfadiazine, is now being evaluated. In the choice of a drug for use in the treatment of acute pulmonary infection, one thinks primarily of its effectiveness against the pneumococcus, which is the most frequent causative agent in pneumonia. However, when chemicals are equally effective against pneumococcus and other organisms that may cause pneumonia, other things being equal, the drug with the widest range of effectiveness is the one of choice. On the other hand, the drug of choice between compounds of similar efficacy is obviously the one offering the least likelihood of producing toxic effects.

In Table 1, we have summarized our evaluation of the toxicity of these four drugs, as well as of their relative effectiveness against the common causative agents of pneumonia. This is based

on our own experience and on the clinical and experimental data available in the literature. Obviously, sulfanilamide should not be used except in hemolytic streptococcus pneumonias, and then only when other drugs are not well tolerated. It is also apparent that until sulfadiazine becomes

TABLE 1 Summary of the Relative Toxicity and Efficacy of Four Sulfonamide Drugs in Infections with the Most Important Organisms Associated with Pneumonia

Drug	RELATIVE TOXICITY	RELATIVE EFFECTIVENESS IN CERTAIN INFECTIONS			
		Pneumo- coccus	Strepto- coccus femoralis	Staphy- lococcus aureus	Fried- lander's bacillus
Sulfanilamide	+++	+	++	0	0
Sulfapyridine	+++	+++	++	++	++
Sulfathiazole	++	+++	++	+++	++
Sulfadiazine	+	+++	+++	+++	++

available,§ the drug of choice in the treatment of pneumonia is sulfathiazole. Recent experience indicates that sulfadiazine has a wider range of effectiveness and is much less toxic than sulfathiazole, it is therefore our present choice for the treatment of pneumonia. The details of our studies with this drug are given elsewhere.<sup>1</sup>

*Route of administration.* Because the danger of renal complications is greater with parenteral chemotherapy, the oral route is always to be preferred. However, an initial intravenous dose of the sodium salt of the drug to be used is indicated in patients who are extremely ill, in those who are comatose, and in those with severe vomiting. Usually, a 5 gm. dose is given to the average adult, and may be followed by 2 or 3 gm. after about six hours. Although it is ordinarily recommended that this be given in distilled water as a 5 per cent solution, we prefer to give it intravenously as a 0.5 to 2 per cent solution in physiologic saline. For subsequent parenteral administration,

§Sulfadiazine has now been released for sale under the Federal Food Drugs and Cosmetic Act. Higher concentrations tend to precipitate out of solution from physiologic saline.

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1941.  
†From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School.

‡Assistant professor of medicine, Harvard Medical School, chief of Fourth Medical Service, and associate physician, Thorndike Memorial Laboratory, Boston City Hospital.

§Research fellow in medicine, Harvard Medical School, assistant resident, Thorndike Memorial Laboratory, Boston City Hospital.

In all cases in which impairment of renal function is suspected, treatment should be undertaken with caution. Urines should be examined and the level of drug determined early in the course of treatment.

In the treatment of patients with pleural complications, it is important to differentiate sterile and infected pleural fluids. For this purpose, thoracentesis is performed, and the fluid obtained is examined for the number and character of the cells and for the presence of organisms in an ordinary stained preparation, and is also cultured. The absence of organisms in the stained smear and the presence of many mononuclear cells are presumptive evidence of a sterile effusion, but this should be verified by culture. In such cases, chemotherapy may safely be discontinued, since sterile fluids are usually absorbed spontaneously. In patients with purulent infected fluids, chemotherapy may be continued for a few days,

FIGURE 1. *Sulfathiazole Fever and Rash.*

In this and the subsequent figures, the following abbreviations are used:

♂ = male; ♀ = female.

SP = sulfapyridine; ST = sulfathiazole; SD = sulfadiazine; NaSD = sodium sulfadiazine.

L.L.L. = left lower lobe; R.L.L. = right lower lobe; and so forth.

C.F. = *pleural fluid*.

PN. I = *pneumococcus*, Type 1; PN. II = *pneumococcus*, Type 2; and so forth.

I.M. = *intramuscular*; I.V. = *intravenous*.

W.B.C. = leukocytes, thousands per cu.mm.; R.B.C. = erythrocytes, millions per cu.mm.

PMN = polymorphonuclear leukocytes.

N.P.N. = nonprotein nitrogen, mg. per 100 cc.

Blood culture: 0 = sterile; + = positive for pneumococcus; numbers represent colonies per cc. of blood; ∞ = innumerable.

but operation should be performed for drainage as soon as it is obvious that the infection is not yielding to treatment.

*Drug fever.* This is a frequent occurrence in patients under sulfonamide therapy and is sometimes difficult to differentiate from postpneumonic complications. Figure 1 shows the chart of a patient with drug fever during the course of chemotherapy. Such drug fever may or may not be

associated with rash and may be accompanied by chills. Frequently, the pulse rate remains relatively low, in spite of the elevation in temperature, and the symptoms of acute pulmonary infection do not recur. The leukocyte count may be somewhat elevated but is usually not very high during the early stages of drug fever. Cases of marked leukocytosis, however, have been noted. The diagnosis of drug fever is justified only when a characteristic rash is present or when the fever subsides within twelve to thirty-six hours after drug therapy is discontinued.

*Use of serum in pneumococcal pneumonias.* It is now generally agreed that sulfonamide therapy is to be preferred to serum therapy in all except the rare cases in which severe toxic reactions pre-

which adequate treatment with the drug fails to bring about the desired result in a reasonably short time, usually twenty-four to forty-eight hours. In some patients with infected purulent complications, adequate control of the infection may not take place until serotherapy is used, and large amounts of serum are often necessary under these conditions.

Obviously, it is impossible in retrospect to evaluate the relative role of each agent in cases in which both drugs and serum have been used. In the patients who survive, reasonable doubts may be raised about the part that the serum played in their recovery. In some of the fatal cases, it is equally reasonable to raise a question concerning what part the serum or the drug played in the

FIGURE 2. Two Patients in Whom Sulfonamide Therapy Was Supplemented by Antipneumococcus Serum.

clude the use of the drugs. Moreover, there is little doubt that the routine use of serum as an adjunct to chemotherapy is unwarranted, since it exposes the patient unnecessarily to the hazards of serotherapy. The differences in clinical response in the great majority of cases do not justify the added expense and effort. The availability of highly effective and relatively nontoxic drugs has now raised the question whether any patients receive sufficient additional benefit from serum to warrant its use as an adjunct to chemotherapy. Doubts concerning the additional value of serum are also based on serologic or statistical comparisons of cases treated with the sulfonamides alone and those in which such treatment is supplemented by serum. We have given long and serious consideration to this problem and believe that a definitive answer cannot be given at this time because of the great difficulty of obtaining conclusive data. Our experience leads us to consider additional serotherapy justified and necessary in individual cases. In general, these include some of the cases with the worst prognosis and those in

fatal outcome. This is particularly true when untoward reactions to either agent are encountered or when serum is given intravenously in the presence of cardiac or circulatory failure.

Figure 2 shows the charts of two patients who recovered after receiving serum in addition to chemotherapy. One patient (F. W.) was practically moribund at the time of admission to the hospital, and his blood was heavily invaded before the first dose of sulfathiazole was given. When serum therapy was started on the morning after admission, the patient had shown no signs of clinical improvement, although the bacteremia was partly but not completely controlled. The patient's condition was so poor that it was believed that the shock of intravenous serum therapy would be sufficient to turn the balance against him. Serum was therefore given intramuscularly, and no reactions resulted. The bacteremia was rapidly controlled, and a balance of antibodies was established within twelve hours after the first intramuscular dose. Although those who attended this patient agreed at the time that serum con-

tributed materially to the patient's survival, it cannot be stated with any degree of assurance that this patient would not have survived under sulfathiazole therapy alone.

It was believed that the other patient (H. M.) was not responding favorably after two days on full doses of sulfapyridine, whereas a dramatic response followed the administration of serum. In

FIGURE 3. *Pneumonia with Bacteremia and an Infected Pleural Exudate, Treated with Sulfapyridine and Serum.*

this patient, the blood had already become bacteria free when the serum was given. One cannot tell with certainty what the course would have been had the serum not been given.

Cases in which failure to respond to chemotherapy was associated with resistance of the pneumococcus to the action of sulfonamide drugs have been described,<sup>4</sup> and it has been shown that in such cases a change from one effective drug to another cannot be expected to be of any help.<sup>4, 5</sup> Such cases do respond in the usual way to the administration of specific antipneumococcus serums. When serum treatment is delayed too long, however, it may prove ineffective.

Figure 3 shows the chart of a patient who illustrates another aspect of the use of serum. The blood was only temporarily rendered free of bacteria under chemotherapy. When serum was administered, the blood was rendered sterile and remained so in spite of the fact that chemotherapy was discontinued. In this patient, the presence of empyema was suspected, but only a small amount of infected fluid was obtained by thoracentesis. Recovery was complete at the time of discharge from the hospital, and surgical intervention was not required. This is another case in which, after serum had been given and the patient had recovered, the specific antibody probably contributed substantially to the recovery, but reasonable doubts may be raised.

The case of A. McL. (Fig. 4) illustrates still another aspect. At the beginning of treatment, this patient seemed to respond favorably; she then

had a relapse of symptoms, and the disease failed to respond to further chemotherapy. In this case, organisms could not be cultivated from the blood during the course of chemotherapy, but they were found in large numbers in the sputum. After the end of the second week of treatment, there developed a marked leukopenia, with complete absence of granulocytes in the circulating blood. Angina followed in spite of the fact that the drug therapy was discontinued. The patient responded to transfusions and pentnucleotide injections with a reappearance of granulocytes, but she had an invasion of the blood with Type 8 pneumococcus and died. It is not possible to say that the fatal outcome would have been averted if serum had been given during the first few days. Nevertheless, one cannot help believing that serum should have been given to this patient early during the relapse, making it possible to discontinue the drug and thus possibly to avert the fatal outcome.

The events in this case also serve to emphasize the value of making frequent blood counts in patients who are treated with sulfonamides for more than a week.

*Treatment of cases with leukopenia.* Because the sulfonamide drugs tend to produce leukopenia

FIGURE 4. *Fatal Agranulocytosis in a Case of Pneumonia Treated with Sulfapyridine.*

and agranulocytosis on prolonged administration, there may be some hesitancy on the part of physicians to give the drugs to patients with low leukocyte counts. It should be emphasized that leukopenia in pneumonia is usually a manifestation of severe infection, and in such cases chemotherapy is definitely indicated. Of course, it must first be ascertained that the leukopenia is not the result of recent therapy with a sulfonamide drug. This is the only absolute contraindication to chemotherapy in the presence of severe infection. Accompanying the leukopenia, there is usually a bac-

teremia Because of the severity of the disease and the usually slow response in such cases, we believe that serum therapy should also be used

An example is shown in Figure 5 The patient was extremely ill on admission, and an initial dose of 4 gm of sulfadiazine was given by mouth A blood count made at the time of admission

FIGURE 5 *Pneumonia and Severe Leukopenia Treated with Sulfadiazine and Serum*

Blood cultures made on admission and again before the first dose of serum were positive, the subsequent ones were sterile

showed that the patient had a white cell count of only 500, but there was a moderate proportion of granulocytes Chemotherapy was discontinued by the house physician on this account, and the results of pneumococcal typing were awaited However, drug therapy was considered to be indicated, and it was therefore resumed twelve hours later with an intravenous injection of 5 gm of the sodium salt of sulfadiazine, followed by regular oral doses Serum therapy was started shortly thereafter The blood culture was positive on admission and again before the first dose of serum was given The patient improved rapidly, but the temperature and pulse dropped only gradually during the next two days, after which the white cell count rose slowly to normal The role of serum therapy in the recovery is hard to evaluate, but one cannot help believing that it was an important factor

Blood cultures and bacteriologic studies of the sputum, including sputum typing, are of great help in prognosis and in the conduct of therapy It is essential to carry these out early if additional serum therapy is to be used successfully

#### SOME SPECIAL USES OF CHEMOTHERAPY IN ACUTE RESPIRATORY INFECTIONS

It is generally agreed that the present sulfonamide drugs are effective only in infections due to the common pathogenic bacteria and are indicated primarily for the cure of infections with such bacteria Nevertheless, it is general clinical experience

that many acute pulmonary infections respond favorably, although no organisms are recovered that are ordinarily considered etiologic in the disease or susceptible to the drugs

*Primary pneumonias of uncertain etiology* In common with many other observers, we have noted many cases of pneumonia that had all the clinical characteristics of typical lobar pneumonia, but cultures of the blood were sterile and examination of the sputum revealed no predominance of pneumococci, hemolytic streptococci, staphylococci or Friedlander's or influenza bacilli When the simple typing methods are resorted to, reports of "no pneumococci" are the rule The predominant organism in the sputum cultures is frequently *Streptococcus viridans* or a streptococcus producing only slight (alpha) hemolysis on blood agar Other organisms, such as *Micrococcus catarrhalis*, may also be found in moderate numbers, and staphylococci or influenza bacilli are sometimes found in small numbers The organisms found are usually nonpathogenic for mice, but occasionally one of the streptococcal strains may invade the blood of a mouse and give a fatal infection Many of these cases respond to chemotherapy in the same manner as typical pneumococcal pneumonias There are other cases with atypical pulmonary consolidation or with x-ray evidence of pulmonary involvement that is considerably more extensive than the physical signs indicate Some of these cases correspond to the ones that have recently been loosely called "virus pneumonias"<sup>6,7</sup> Such patients usually fail to respond to chemotherapy in adequate doses

In the patients who do respond, there is the likelihood that a pneumococcus was the responsible agent but was not recovered in the bacteriologic study The commonest cause for the failure to identify the pneumococcus is the failure to obtain proper sputum for the bacteriologic examination

From the practical point of view, it seems worth while to begin chemotherapy in all such cases and to discontinue drugs if after about forty-eight hours there is no definite evidence of improvement in the clinical course Further treatment subjects these patients to all the possible disadvantages of chemotherapy without offering much hope of beneficial effects

*Secondary pneumonias* We have been much impressed recently with the beneficial effects that may be obtained from chemotherapy in patients with acute pulmonary infections complicating severe and intractable asthma or a severe cardiac failure that does not respond to the usual therapy The administration of sulfonamides in such cases

is frequently accompanied by a drop in fever and pulse rate, and the underlying disease yields rapidly to proper treatment.

In Figure 6 are shown charts of 7 patients with asthma who had received all the usual therapy for this condition without effect. In each case, there were slight to moderate fever and leukocytosis. The physical signs varied. Some patients had only the usual signs of acute asthma, whereas others had moderate areas of consolidation, particularly in the base of the lungs. The first improvement of the

or in others who later prove to have pulmonary tuberculosis, there may occur acute exacerbations in the pulmonary symptoms, with dyspnea, fever, pleural pain, leukocytosis and the appearance of new areas of consolidation in the lungs. In such cases, these signs and symptoms are often due to superimposed bacterial infection, which yields promptly to chemotherapy, leaving the underlying tuberculosis unaffected. Possibly extension of the tuberculosis is averted or limited by such treatment. An example of a case of this sort is shown

FIGURE 6. Seven Cases of Severe Acute Bronchial Asthma with Accompanying Acute Pulmonary Infections, Treated with Sulfonamides.

asthma occurred after the patients were given full doses of sulfonamide drugs, and coincided with the drop in fever. These are not cases that are ordinarily included among the pneumococcal pneumonias. In most cases, pneumococci were not recovered, the bacteriology of the sputum was similar to that of the cases just described, and blood cultures yielded no growth.

A group of 3 cases with congestive cardiac failure in which a dramatic response of the cardiac symptoms occurred only after chemotherapy is shown in Figure 7. There was fever in each case. The physical signs may have been attributable to pulmonary congestion or to pulmonary infection. In any event, these signs began to clear soon after sulfonamide therapy was started, and improvement in the symptoms of congestive failure followed rapidly.

In patients with known pulmonary tuberculosis

in Figure 8. The response in this patient was very similar to that usually seen in patients with acute pneumococcal pneumonia. The patient proved to have extensive pulmonary tuberculosis with a positive sputum, but the fever and symptoms subsided rapidly following treatment with sulfapyridine.

The course of events in the last case also serves to emphasize the advantage of following very carefully the fluid intake and output of patients receiving chemotherapy, regardless of the indications for the use of the drug. In this patient, there was a complete suppression of urine at the end of the second day of chemotherapy, after what seemed to be a good response of the acute infection. The patient was given large amounts of fluid parenterally and frequent injections of 50 per cent glucose intravenously without effect. Cystoscopy was performed after sixteen hours. Sulfapyridine crystals

were found in the bladder, in the left ureter and in both kidney pelvis; in fact, the left ureter was

the sulfonamide drug was effective in clearing up the acute pulmonary infection. The routine use

FIGURE 7. Three Cases of Congestive Cardiac Failure with Fever, Treated with Sulfonamides.

completely obstructed by clumps of these crystals. Ureteral catheters were inserted into the pelvis of the kidneys and kept in place for twenty-four

of sulfonamides in the treatment of asthma, cardiac failure or pulmonary tuberculosis is not recommended. In the absence of definite acute bacterial infection, no beneficial effects are to be anticipated, and the patient is subjected unnecessarily to the treatment. Furthermore, even in the presence of infection, the sulfonamides must be used with great caution to avoid untoward effects. In such cases, sulfonamide therapy should be discontinued in two or three days if the acute infection is not influenced, and should not be maintained for long periods in any event.

\* \* \* \*

In this brief presentation, it has been possible to consider only a few of the important problems concerning chemotherapy in pneumonia and to indicate some related situations in which the newer sulfonamides may be of great benefit.

## CARCINOMA OF 'THE ENDOMETRIUM'

## A Review with Results of Treatment Through 1935

GEORGE VAN S. SMITH, M.D.<sup>†</sup>

BROOKLINE, MASSACHUSETTS

IT HAS seemed to the members of the staff of the Free Hospital for Women that a clearer and broader perspective of our experiences with different forms of cancer is gained if we include in our periodic surveys the cases already reviewed in earlier studies, for longer follow-up gives new information about the survivors and, besides, patients formerly untraceable have in recent years been found in sufficient numbers to change appreciably the previous figures. Furthermore, evaluation of treatment can perhaps be better made by comparing earlier with later results in cases managed in the same clinic because of greater familiarity with the cases and a uniform method of reviewing them.

The present survey, which takes the place of previous publications on this subject from this hospital,<sup>1, 2</sup> the last of which carried five-year results through September, 1927, deals with 307 consecutive previously untreated<sup>‡</sup> cases of carcinoma of the endometrium seen from May 1, 1903, through December 31, 1935.<sup>§</sup> In every case, the diagnosis was made or confirmed by microscopic examination. For this writing, the pathology has been completely and critically reviewed, with the generous assistance of our pathologist, Dr. Arthur T. Hertig, and, through him as occasion demanded, of Drs. S. Burt Wolbach and Shields Warren.

## DATA CONCERNING PATIENTS

The youngest patient in this series at the time of treatment was thirty-three years of age, the oldest, eighty-five. Eighty-four per cent of the patients were over fifty, and 44 per cent over sixty. Forty-one per cent were nulligravidas. Eighty-five per cent had ceased menstruating.

*Relevant past history.* Three patients had had both ovaries removed fifteen, seventeen and thirty years respectively before admission. At the time

\*From the Free Hospital for Women.

<sup>†</sup>Assistant professor of gynecology, Harvard Medical School, visiting surgeon and director of the Fearing Research Laboratory, Free Hospital for Women.

<sup>‡</sup>During this same period, 15 patients who had had their primary therapy elsewhere received further treatment here. Eight died of recurrence less than five years after first treatment; 2 died of recurrence six to seven years after first treatment, 2 were well at eight and twelve years, having received prophylactic irradiation here; and 3 were well seven, nine and ten years after radium applied here for biopsied vaginal recurrence nineteen to thirty months after hysterectomy elsewhere.

<sup>§</sup>Omitted from consideration herein are 16 cases so diagnosed prior to May 1, 1903, because no pathological confirmation is available.

of castration, they were all under forty-three years of age. Five had had a radical mastectomy eight months to fourteen years previously. Curettage for abnormal bleeding had been performed on 13 patients five to thirty-three years before entry. A story of x-ray treatments for fibroids and flowing three years and six months to nine years before admission was given by 3. Five patients, 4 of them our own, had been treated successfully by radium (600 to 2400 mg. hr.) for flowing and endometrial hyperplasia, two to nine and a half years previously, and this diagnosis had recently been confirmed for all of them.

Of more immediate significance is the following past history. One patient had been taking ergot for six months for flowing that occurred fourteen years after the menopause. Another had had cysts of the ovaries removed for flowing at the age of fifty-eight, two years before hysterectomy here. A third had had a right salpingo-oöphorectomy for bleeding at the age of fifty-nine, six weeks before admission. Repeated x-ray treatments had been given for flowing to 3 patients for as long as three years without diagnostic curettage. Seventeen women gave a story of curettage one to twenty-four months before admission. Four had had curettage seven to thirty-six months previously, and the tissue had been reported not malignant. Despite persistent flowing, nothing further was done. Thus, about 9 per cent of the whole series had been mismanaged, with resultant delay of proper treatment, if their histories are entirely reliable. If careful examination under anesthesia with curettage of uterine cavity and endocervix and the taking of specimens for biopsy from suspicious areas of the cervix fail to reveal the cause of abnormal bleeding, dogged follow-up is demanded. Recurrence of bleeding thereafter requires immediate hysterectomy, unless a benign cause becomes clearly demonstrable.

*General physical examination.* As would be expected in a group of women for the most part past middle age, there were many in poor condition. Adequate physical examinations are recorded for 250 of the series, 56 per cent of whom had systolic blood pressures of 150 to 260; 28 per cent weighed 160 pounds or over, the heaviest pa-

patient weighing 276 pounds. Four per cent of the whole series had diabetes, 8 per cent had gall stones, proved by palpation at operation, and this figure is surely low, since the upper abdomen was not explored at every laparotomy and no gall bladder studies were performed on the majority of patients who did not come to abdominal operation. One patient had a duodenal ulcer, and only 1, a nulligravida, had procidentia. Arteriosclerosis was not often recorded, but it must have been rife. This assumption is borne out by the fact that the majority of later deaths not due to recurrent cancer were ascribed to vascular accidents and diabetes.

### TREATMENT

Tables 1, 2 and 3 summarize treatment and results. Removal of tubes and ovaries was included in all the hysterectomies. Thirteen patients were

were for other indications in younger women, 4 of whom had early, unsuspected endometrial carcinoma.

**Radiation** It was because of operative risk, obviously hopeless disease or both that radiation alone was employed in 36 cases. In the majority, only local palliation was expected. The "cures" by radiation alone were, apparently, the result of two purely chance occurrences, namely, that adequate radiation happened to reach all the growth and that the tumor happened to be radiosensitive. Before 1931, most patients treated by radium alone received single applications of 2400 mg hr. Three of the 5 surviving five years, however, had had 4800 mg hr. The capsules of the element in 0.5 mm of silver were placed, until 1926, in rubber tubing and, until 1931, in brass tubes of 0.5 or 1.0 mm thickness and inserted into the uterus. Between 1931 and 1935, inclusive, the radium was

‡In 1 patient the omentum was resected for a blood clot metastasis at the time of hysterectomy. 1 patient had metastases to the right tube and ovary at the time of hysterectomy. 1 patient had a carcinosarcoma of the endometrium. 1 patient also had in the myometrium a malignant tumor derived from an embryonic rest.

untreated because of hopelessly advanced disease, which was not determined in 9 until exploratory laparotomy. Three of these died postoperatively.

**Supravaginal hysterectomy** Obesity, cardiovascular disease, old age, fixation of the cervix and lower uterus deep in the pelvis by adhesions, shrunken supports or by scarring from inflammation and hopeless extension or metastasis, alone or combined, were the usual reasons why only supravaginal hysterectomy was performed on 69 patients of this series. A coring out of the cervix was included in 19, the first being done as early as 1906. Five of the supravaginal hysterectomies

applied in tubes of 1.0 mm of brass and 1.0 mm of lead for totals of 2200 to 4800 mg hr, these totals being reached in 8 cases by two treatments given two to four weeks apart. Before 1931, radiation was given to only 4 patients following operation, in total doses of 600 to 1800 r over a period of weeks. Since the group is so small and the value of the radiation as then administered so questionable, the cases are not considered separately.

**Preoperative radiation** Until 1931, radiation was not used as a primary treatment in conjunction with operation. Since radium had been of real

value in 5 of the cases unsuitable for surgery and in some cases with vaginal recurrences, a decision was made to employ it as a supplementary and prophylactic measure before or after hysterectomy. When used preoperatively, the capsules were placed in tandem in a tube of 1.0 mm. of brass and 1.0 mm. of lead from the top of the uterine

we are grateful for full co-operation. Portals of entry varied from 10 by 10 to 20 by 20 cm.; target distance was 50 cm.; filtration consisted of 0.5 mm. of copper and 1.0 mm. of aluminum; kilovoltage was about 200, and milliamperage 5 to 8. The great majority of individual treatments were of 400 r. Treatments were usually given daily for

\*Following exploratory laparotomy  
†Patient died of acute empyema of the gall bladder 21 days after the first radium treatment (weight 198 pounds, blood pressure 246/130).  
‡One patient also had primary carcinoma of the left ovary  
§One patient also had a primary carcinoma of the right ovary.

extensions beyond the sphere of radium's influence and, secondly, to reduce perhaps the chances of operative dissemination of the disease without causing in itself significant damage. During the period covered by this report, x-ray therapy was administered by Dr. John W. Meachen, to whom

months after the first for a total of 4800 r. During 1931 and the early months of 1932, some patients received as much as 5400 r in their first two series, the third bringing the total to 7000 r.

There have been, and still are, no definite indications to follow in the selection of cases for pre-

operative radiation. Some cases were so managed arbitrarily. With a few patients, however, this procedure allowed time to carry out regimens aimed at making them better operative risks. Moreover, when the uterus was considerably enlarged by tumor, it seemed that the shrinkage and drainage resulting from irradiation would facilitate operation. When there was cervical or vaginal involvement, preoperative radiation seemed clearly indicated.

*Postoperative radiation.* Between the second and tenth weeks of convalescence, a cylindrical "bomb," of 1.0 mm. of brass and 2.0 mm. of lead, containing 100 mg. of radium, was packed transversely across the vaginal vault, and allowed to remain for fifteen to thirty hours, the majority of doses being of 2000 or 2400 mg. hr. Postoperative x-radiation was started within eight weeks of operation, the technic, dosage and timing being as above described. Oftener than not, the first series of x-ray treatments preceded radium application.

Since 1935, combined x-ray and radium therapy has been employed practically routinely before or after operation and for those patients not considered eligible for operation. Radium dosages have been larger, at least 3000 mg. hr. preoperatively or at least 2400 mg. hr. postoperatively, and two applications two to eight weeks apart, totaling 4800 to 6000 mg. hr., for those not operated on. Since the fall of 1937, x-ray treatment, administered by Dr. Richard Dresser, has been given in a single consecutive series. Moreover, regardless of the sequence of therapy elected, an attempt has been made to complete all treatment within eight weeks.

#### OPERATIVE AND PATHOLOGICAL FINDINGS

*Extent of cancer of the endometrium.* In addition to the 13 patients whose disease was considered too extensive for treatment, 4 had vaginal metastases on admission, and 12 had adjacent or distant peritoneal spread. The disease was locally advanced, with fixation of the uterus in 10 cases; in 13 it had reached or grown through the uterine serosa. One patient without extensive local tumor had a presumed liver metastasis. Six cases had apparently localized ovarian metastasis, 1 of which also had a primary carcinoma of the opposite ovary.

*Associated malignant tumors.* One patient had an axillary recurrence of breast cancer on admission. Another underwent radical mastectomy here for carcinoma of the breast with axillary-node involvement, at which time intrauterine radium was applied as a preliminary to later hysterectomy. There was a concomitant inoperable squamous-

cell cancer of the cervix in 1 patient, and in 2, additional pathological study accidentally disclosed very early cancer of the cervix. One patient had four primary tumors—carcinomas of the ovary, cecum, ascending colon and endometrium. In all, 8 patients had a primary carcinoma of the ovary as well as primary endometrial neoplasm. Associated malignant neoplastic disease was present in 3 other patients: a rapidly growing fibrosarcoma of the cervix, a rapidly growing fibrosarcoma in a fibroid and a malignant embryonic rest tumor in the myometrium. Thus, 16 patients, or 5 per cent of the whole series, had more than one primary malignant tumor at the time of entry. Even though the data of this and the preceding paragraph are weighed optimistically, one is forced to conclude that at the very least 15 per cent of the whole series had an obviously poor prognosis when treatment was instituted. As shown in the charts, however, a poor outlook does not necessarily presage a fatal outcome, a fact that helps to maintain optimism in treating this disease.

*Other associated pathologic lesions.* Pelvic inflammation, chronic or with subacute exacerbation, was present in 45, or 17.4 per cent, of the 258 patients undergoing hysterectomy; fibroids were present in 79, or 30.6 per cent. Diffuse adenomyosis of the uterine wall was found in 5 cases, hemangioendothelioma of the broad ligament in 1 and a carcinoid of the appendix in 1. Benign conditions of the ovary were discovered as follows: pseudomucinous cystadenoma, 3; papillary serous cystadenoma, 3; dermoid, 2; fibroma, 2; endometrioma, 3; beginning papillary cystadenoma, 8; cystadenofibroma, 6; granulosa-cell tumor, 2; thecoma, 2; and bilateral thecoma, 1.

In examining the sections of the ovaries, I was impressed with the frequency of stromal-cell or thecal-cell activity, even to diffuse thecal-cell hyperplasia. Eighty-seven per cent (156 cases) of the available postmenopausal ovaries (180 cases) that were not involved by cancer or benign tumor had what was interpreted as slight to marked thecal-cell activity. One would expect such activity to indicate production of estrogenic hormone, and to be accompanied by corresponding endometrial proliferation, which, however, was not found to any striking degree in the available sections. Sections of endometrium had been prepared from 62 of the postmenopausal cases with apparent activity of the ovarian stroma and showed the following: atrophy, 14; slight proliferation, 35; definite proliferation, 11; and hyperplasia, 2. No correlation between the amount of stromal activity and the amount of endometrial activity was ap-

parent. Of course, the extent of the cancer made it impossible to obtain sections of the endometrium in a greater number of cases and in the above did not allow much choice of area to be sectioned. Moreover, in some cases it seemed that the proximity of the cancer itself gave the endometrium a little stimulation.

The relatively frequent association of endometrial cancer and granulosa-cell tumor appears to substantiate the opinion that continued estrogenic stimulation may carry endometrial hyperplasia on to cancer. The observation of a high percentage of thecal-cell activity in postmenopausal ovaries may perhaps be interpreted as indicating prolonged estrogenic stimulation of a degree insufficient to bring about significant endometrial proliferation, but it also involves the possibility of a reciprocal relation between ovary and endometrial cancer, namely, that the cancer itself may play a part in producing the ovarian change. It should be emphasized that thecal-cell hyperplasia is not in itself peculiar to the ovaries of elderly women with this type of cancer, being seen in various other conditions, but rather that there appears to be more hyperplasia associated with this disease.

Sections of the endometrium had been made from a total of 82 postmenopausal cases. In 62, the ovaries showed thecal-cell activity, as described above, in 12 they were atrophied, and in 8 no ovarian sections had been taken. The endometrial sections from all cases showed the following: atrophy, 22; slight proliferation, 45; definite proliferation, 13; and hyperplasia, 2.

Only 22 cases of the whole series had endometrial polyps, which were found in uteri with less advanced tumor. Many of the cancers themselves hung from the upper uterine cavity as polypoid masses, suggesting origination in a polyp. It is likely that this form of cancer starts in polyps oftener than can be demonstrated.

*Tumor pathology.* The malignant tumors were typed histologically as follows, the percentage of patients alive at five years being included in parentheses after each group: adenocarcinoma, 161 cases (62 per cent); adenocarcinoma with varying amounts of alveolar massing of undifferentiated cells, 115 cases (49 per cent); adenocarcinoma intermixed with more or less squamous-cell carcinoma, that is, adenoacanthoma, 25 cases (48 per cent); carcinosarcoma, 3 cases (33 per cent); squamous-cell carcinoma, 2 cases (100 per cent); and adenoacanthosarcoma, 1 (0 per cent). This typing is at best only roughly accurate concerning the first two groups, and depends in good part on the number of sections that happened to be taken from different portions

of the same tumor. For example, some sections from a tumor appeared to be purely adenomatous, whereas, others from the same tumor showed masses of undifferentiated cells or even areas of squamous-cell cancer. More sections from individual tumors might have changed the classification considerably.

Difficulties were also encountered in attempting to correlate the microscopic degree of malignancy with the duration of symptoms, the gross extent of the disease and the length of survival. It could not be shown that duration of symptoms or microscopic grade of malignancy bore any constant relation to the extent of the disease at the time of treatment or to the length of survival. In the first place, the degree of malignancy often appeared to vary in different areas of the same cancer. Secondly, duration of symptoms involved other factors besides the rate and extent of cancer growth. Some patients with advanced growth had had symptoms for only a short while, owing to cervical or vaginal atresia. Others, with protracted flowing, had highly active tumors still confined within the uterus, which apparently had formed a distensible but impervious barrier. Other cases, with tumors of low microscopical malignancy, had metastases without especially advanced local growth. A rare patient with confined tumor of not too high microscopical malignancy succumbed to exceedingly rapid recurrence without any change in the microscopical appearance of the tumor. Recurrences usually looked more active than the primary neoplasm. In others, whose cancers were of relatively high activity microscopically, the growth of recurrences was slow, sometimes to great size locally, death occurring as late as twelve years and eight months after operation.

Regardless of microscopical malignancy, it is difficult to understand why surgery alone should have cured a case with omental metastasis or with a surface metastasis to an ovary. In such cases, cancer cells must have been more widely disseminated and something must have prevented their "taking." The patients whose clinical courses failed to progress according to prognosis based on operative and pathological findings, for example, rapid recurrence of grossly confined, microscopically low-malignancy cancers or cures despite proved metastasis at the time of treatment, suggest that unknown constitutional factors either enhance or weaken resistance to endometrial cancer or cause the cancer itself to vary greatly in its malignancy, all regardless in general of the microscopical picture.

## RESULTS

One hundred and seventy one patients, or 55.7 per cent of the whole series of 307 cases and 58.1 per cent of the 294 treated cases, were alive at five years. Eighty five patients, 43.5 per cent of the 195 seen from 1903 to 1930, inclusive, and 45.4 per cent of the 187 who were treated, were alive at the ten-year interval. No attempt has been made to correct the survival figures because of the uncertainty regarding patients who died of intercurrent disease. Without autopsy they may not be considered free of recurrence. To simplify the figures, these and the untraceable patients are rated as dead of recurrence. Because 3 patients died of probable recurrence between twelve and thirteen years after operation, survival for at least thirteen years appears to be the criterion for absolute cure.

Of all the patients treated before 1931, 108 were alive at five years. Five became untraceable, 8 died of intercurrent disease, and 10 died of recurrence before the ten-year interval; 4 were living with recurrence at ten years. Thus, 75 per cent of those alive at five years were known to be alive and apparently free of disease at ten years.

As shown in the tables, the results for the years 1931 to 1935, inclusive, are no better than those of earlier years, despite the fact that 71 cases of this group, 66 per cent of the total treated, had had radium or x-radiation, or both, along with surgery. Forty-seven, 66 per cent, of these 71 patients were alive at five years. With surgery alone, however, practically as good five-year results were achieved. The failure to save more patients of this last group cannot be attributed to any change in operative technic and is probably explained as follows: 32 per cent had, at the time of treatment, extension of the disease, metastasis or another primary malignant tumor, as compared with 17 per cent of the cases listed in Table 1 and 22 per cent of those in Table 2. Although the extra manipulations and the delays attendant on pre-operative irradiation have been considered possible factors contributing to the unimproved results, it is more probable that the figures would have been poorer if irradiation had not been given. Furthermore, 6 of these 71 patients died quite definitely of intercurrent disease before five years. Although any advantage of supplementary irradiation cannot be demonstrated unequivocally, it is thought to have been of value. Of possible significance is the fact that only 4 of these, 5.6 per cent, had vaginal recurrence, as compared with 12, 6.3 per cent, of the 187 patients treated by operation only, and all these 4 patients had had advanced growth

locally when first treated. Two, 5.5 per cent, of the 36 treated only by irradiation had vaginal recurrence.

Evaluation of irradiation alone in this series may not be made, since it has not been employed in a sufficiently large number of unselected patients.

## OPERATIVE MORTALITY AND COMPLICATIONS

There were no operative deaths following supra-vaginal hysterectomy. Four patients developed incisional hernias, and 1 a vesicovaginal fistula, which was easily repaired.

Twelve, 6.3 per cent, of the 189 patients undergoing complete hysterectomy died postoperatively, 6 of pulmonary embolism, 4 of peritonitis and 2 of shock. Three patients developed incisional hernias, and 2 vesicovaginal fistulas, which were repaired satisfactorily.

No deaths or complications could be attributed to the use of radium alone. One death was assigned to the combination of radium and x-radiation:

Mrs E M I, at the time of complete hysterectomy on August 4, 1931, had metastatic cancer in the posterior vaginal fornix and the pouch of Douglas. Radium, 3000 mg hr, was applied to the vaginal vault 6 weeks later, following which 2700 r of 200-k.v. radiation was given. The same dose of x rays was administered 2 months later, and 2½ months following this, 2500 r were given, making a total of 7900 r within 6 months. Because of pelvic induration, thought at that time to be recurrent disease, and despite the fact that the patient felt quite well and was gaining weight, another radium treatment (2400 mg hr) was given. Increased pelvic induration and stricture of the rectum ensued, with disabling symptoms. Colostomy was performed elsewhere 2 years after operation, and death 8 months later was attributed to cancer of the rectum. From the course so long as followed in this clinic, it is probable that overirradiation caused death.

Severe proctitis without later disability occurred in 2 patients who received, following complete hysterectomy, 2400 mg hr. of radium, and 7000 r and 4800 r of x radiation, respectively. No fistulas have yet resulted from the irradiation given. There were only a few cases of transient irradiation cystitis.

*Retreatments.* Twenty four patients were treated by radiation for recurrence from a few months to nearly five years after first therapy. Eleven had vaginal, 1 a cervical, recurrence following operation only; 4 had vaginal recurrence after operation in addition to radiation, and there were 2 vaginal and 6 intrauterine recurrences after irradiation only. Only 1 remained permanently cured; 7 lived for six to nearly eleven years from first

treatment; 2 are alive, 1 with recurrence at eight years and six months, and 1 being well at nine years and three months. Recurrence after five years was in every case beyond any hope of palliation by local treatment.

*Associated malignant tumors.* It is known that 3 of the patients who had had a radical mastectomy before admission had mammary carcinoma. Sixteen more, as described above, had associated primary neoplasms at the time of treatment here. Two patients developed a new primary cancer following treatment of their endometrial cancer. In the first, a carcinoma of the ascending colon was removed two years and six months afterward. She is now well four years and two months after right colectomy. In the second, a primary carcinoma of the urinary bladder was found three years and eight months afterward, despite, or conceivably because of, the irradiation she had had previously. Further radiation and operation were of no avail, and she died fourteen months later. Thus, 21 patients of this series, or 6.8 per cent, had proved multiple neoplasms.

#### STATUS OF TREATMENT

From the results presented, it appears that complete hysterectomy, with bilateral salpingo-oophorectomy and removal of at least a small cuff of vagina, is still the primary desideratum in the treatment of cancer of the endometrium. The operation should include preliminary closure of the external os by suture to prevent possible spill of viable tumor, ligation of the tubal ostia for the same reason immediately on opening the abdominal cavity, and the avoidance so far as possible of direct trauma to the uterus during removal—for example, by applying clamps to the broad ligaments instead of grasping and thereby lacerating the fundus by instruments of traction, for fear of opening up channels of dissemination. These maneuvers have been practiced in the great majority of the complete hysterectomies herein summarized, along with a wide excision of the broad and infundibulopelvic ligaments. The fact that patients die of recurrence in spite of these precautions, even when the tumor is apparently confined within the uterus and the removed tissues show no microscopic metastases, suggests the possibility that the disease may be spread sometimes through uterine veins or lymphatics below the clamped portion of the broad ligaments by the motions necessitated during removal. This consideration intimates that clamping of the whole length of the parametria down to the vaginal vault as early as possible in the operation may be another worth-

while precautionary measure, for the accomplishment of which the vesicouterine flap and bladder would first have to be freed.

Improved results are being reported in small series of cases from the use of radium and x-rays alone. Perhaps if we treated a consecutive series with irradiation alone we could better our results. Of this we are skeptical, for of 24 cases (Table 3) receiving radium with or without x-rays on an average of a little over six weeks before operation, only 4 showed no evidence of the disease in the sections taken from the operative specimens. All had had 2400 to 3600 mg. hr. of radium, and 16 had received 1600 r of x-ray therapy as well. Admittedly, this is about half of what is here considered an adequate dose, but in recent years we have had the same experience with a number of cases in which full irradiation was used. These patients were at first thought unsuitable for operation. Five to fourteen months after full irradiation and general medical measures, a feeling of uncertainty led to operation, and in half the cases cancer was still present. We are not at all convinced that irradiation alone as now administered can supplant surgery in attacking this type of cancer.

Since, however, radium has been lifesaving in some patients with postoperative vaginal recurrence and, alone or with x-rays, has clearly prolonged life, we believe that, combined with x-radiation, it should be employed routinely, either before or after operation. When applied preoperatively, it should be so distributed as to affect the upper vagina as well as the whole length of the uterus.

#### SUMMARY AND CONCLUSIONS

A series of 307 consecutive, previously untreated, pathologically confirmed cases of carcinoma of the endometrium seen from May 1, 1903, through December 31, 1935, is reviewed with reference to past history, physical condition, treatment, operative and pathological findings, results, operative mortality, complications, retreatment for recurrence and associated malignant tumors. Previous irradiation for functional uterine bleeding in 8 cases did not inhibit the development of endometrial cancer. According to history, delay of proper treatment, which might have been prevented by the first physician consulted, occurred in 9 per cent of the series. Only 1 patient had procidentia. Five per cent of the series had more than 1 primary cancer at the time of treatment, and 6.8 per cent thus far have had proved multiple malignant neoplasms.

The observation has been made that a high per-

centage of postmenopausal ovaries in cases of this type of cancer show varying amounts of thecal cell hyperplasia, even to the extent of near thecoma formation, without, however, commensurate proliferation in the sections of endometrium that were available

No significant relation could be demonstrated between duration of symptoms, microscopic form or grade of malignancy, extent of cancer at the time of treatment and length of survival

Of all treated patients, 58.1 per cent were alive at five years. Of those treated before 1931, 45.4 per cent were alive at ten years. Of those living five years after treatment, 75 per cent were known to be alive and apparently free of cancer at ten years. Survival for at least thirteen years appears to be the criterion for absolute cure in this type of cancer.

One death was attributed to overirradiation. The combination of radium and x radiation produced a few temporary, nondisabling complications

Of 24 patients treated by irradiation for biopsied local recurrence less than five years after primary therapy, 12 were alive at five years, 2 survived for ten years and 1 was well at fifteen years

Although in this series irradiation alone has not been employed in a sufficient number of unselected cases to allow proper evaluation, from our experience with patients operated on following irradiation we believe that it cannot supplant surgery

Preoperative or postoperative application of radium and x radiation are considered valuable and probably necessary adjuncts to the best management of endometrial cancer, despite the failure to demonstrate in this series unequivocal improvement of results from their use

## GLAUCOMA AND THE GENERAL PRACTITIONER\*

PAUL A CHANDLER, M.D.

BOSTON

GLAUCOMA causes about one third of all blindness in patients past middle life. A large percentage of blindness from this cause is preventable by recognized methods of therapy, provided the treatment is begun early. Because physicians in general medicine and surgery can play an important role in the control of glaucoma, this communication is presented.

In this discussion, I shall attempt to explain how glaucoma causes blindness, to review the diagnostic symptoms and signs, to describe briefly the treatment, and to point out how physicians may help in the prevention of blindness from this cause.

#### ETIOLOGY

Glaucoma means an intraocular pressure too high for the eye to withstand safely. Fluid is constantly passing into the eye through the ciliary processes and passing out again through Schlemm's canal. In the normal eye, the intake and outlet of fluid is so beautifully balanced that the intraocular pressure is maintained at a level of about

20 mm of mercury. In glaucoma, there is either an excessive inflow, or a blockage of the outflow, so that the pressure in the eye rises.

There are various theories concerning the etiology of glaucoma, but this problem is still unsolved. When the pressure in the eye is elevated for a long time, loss of vision results. If the pressure is extremely high, loss of vision is rapid. If the pressure is only moderately elevated, the loss of vision takes place more slowly. In either event, if the intraocular pressure is not controlled, the end result is total and permanent blindness.

Figure 1, which presents a series of visual fields, shows how vision is gradually lost from chronic glaucoma. In this disease, as the field charts indicate, the loss of vision is first in the periphery of the field. In many cases, central vision, or reading vision, is maintained until the disease is in the most advanced stage. Thus, the patient may not be aware of trouble until a large portion of the field of vision is lost.

Glaucoma may be primary or secondary. It is called secondary glaucoma when it is due to some obvious disease of the eye, such as iritis, uveitis, intraocular hemorrhage and certain forms of cataract, or to some operation on the eye, such as that

Presented at the annual meeting of the New Hampshire Medical Society, Manchester, May 13, 1941.  
Fellow in ophthalmology, Harvard Medical School; surgeon, Massachusetts Eye and Ear Infirmary.

for cataract. Although secondary glaucoma is sometimes the more difficult and intractable form, I need not discuss it here, for the patient is usually already in the hands of the ophthalmologist when this complication arises.

Primary glaucoma, which comes on without any obvious cause, is the type considered in this paper. It may be acute or chronic. These two forms are so different in their manifestations as

FIGURE 1. Chart Showing Progressive Impairment of the Visual Field in Untreated, or Inadequately Treated, Chronic Glaucoma.

*Most eyes take the course as shown by the field charts in the left column: here it can be seen that central vision is maintained until a very late stage in the disease. Rarely central vision is lost early, as shown in the field charts in the right column.*

almost to constitute two separate diseases. Figure 2 illustrates the difference between the two types. Thus, in acute glaucoma, the tension between attacks is not merely *almost* normal, but is, in fact, *absolutely normal*. Then comes a sudden rise in tension, to a greater or less degree, depending on the severity of the attack. In the chronic form, on the other hand, although the tension may vary greatly at various times, for practical purposes it can be said that the tension never

reaches the normal level. The eye is constantly subjected to various degrees of increased pressure, and this results in permanent structural changes in the eye, especially cupping of the optic disk, which causes a gradual loss of visual field.

#### SYMPTOMS AND SIGNS

In a typical case of acute glaucoma, there is often a history of mild prodromal attacks. These mild attacks may last from one to several hours; they are characterized by slight to moderate discomfort in the eye and blurred vision of varying degree, and the patient may see colored halos around lights. From such an attack, the patient may recover spontaneously, with the eye symptom free and as good as ever. Then comes the severe attack, from which there is no spontaneous recovery. With this, there is severe, often agonizing pain, rapid and profound loss of vision, and unusually uncontrollable nausea and vomiting. On examining the eye, one finds more or less congestion, a dull steamy appearance to the cornea, a shallow anterior chamber and a pupil that is nearly always partially dilated and fixed. On palpation, the eyeball feels much firmer than that of the unaffected eye.

Acute glaucoma must be differentiated from acute iritis. Severe pain, loss of vision and congestion of the eye may all be manifestations of acute iritis. In cases of iritis, the pain is usually less severe and comes on more gradually, and nausea and vomiting are absent. Aside from actual determination of the tension, the most reliable differential diagnostic point is the size of the pupil, which is larger than normal in glaucoma and smaller than normal in iritis. In acute glaucoma, the terrific pressure in the eye causes a temporary paralysis of the sphincter of the iris, and the pupil becomes larger than normal. In acute iritis, the engorgement and irritation of the inflamed iris cause spasm of the sphincter of the iris, and the pupil becomes smaller than normal.

In chronic simple glaucoma, the symptoms are not of much help in making the diagnosis. The patient may complain of mild pain in the eye, and of periods of blurry vision for hours or days. He may see colored halos around the lights at night. He may complain of seeing poorly in dim light, and of slowness to adapt when going into a darkened room. On the other hand, most patients have no complaints whatever until the disease has reached a relatively advanced stage.

Three signs are of chief diagnostic value: increased intraocular pressure, cupping of the optic disk and characteristic changes in the visual field.

To the well-trained ophthalmologist, the diag-

nosis of chronic glaucoma usually presents no difficulty. The intraocular pressure is accurately measured with a tonometer, the cupping of the disk is recognized by ophthalmoscopic examination, and the visual field defect is easily mapped out. There is no ocular disease with which chronic glaucoma need be confused.

### TREATMENT

An attack of acute glaucoma should be regarded as an emergency. If adequate treatment is begun within a few hours of the onset of the attack, vision is usually preserved. The later the treatment is begun, and the more inadequate it is, just so progressively worse becomes the prognosis. Forty

taken without delay, even though the operative risk to the eye in the presence of marked congestion and high tension is not inconsiderable and the operation is more difficult to perform. In some of these cases, classic iridectomy may relieve the condition only temporarily, if at all, and further operation may be required. In the late cases, all the efforts of the ophthalmologist may fail.

Aside from the difficulties in satisfactorily lowering the tension in the late cases, there is another even more important reason for instituting early treatment. Eyes vary greatly in their vulnerability to high tension. All ophthalmologists have seen eyes that have been subjected to a high

FIGURE 2 Diagram Indicating the Differences in Behavior of Intraocular Pressure in Acute and Chronic Glaucoma

*In acute glaucoma, the tension is always normal until the sudden rise in pressure during an attack. In chronic glaucoma, the tension may vary greatly, but is usually above normal.*

eight hours after the onset of the attack may be considered a sort of deadline, for if the beginning of proper treatment is delayed beyond this period, the prognosis is relatively poor.

The ideal treatment consists in lowering the tension to normal with pilocarpine or some other eye drop to constrict the pupil, and a few days later, when the eye is quiet, performing an iridectomy. If this is done, nine such eyes out of ten will remain completely and permanently cured. When the tension has been brought to normal with a miotic drug, both physician and patient may be reluctant to consider an operation. Except in very old patients, I believe that it is a serious mistake not to do an iridectomy, for without it, even with the continued use of drops, further acute attacks are almost certain to occur. It is not known exactly how the operation of iridectomy prevents the attacks in these cases, but the experience of generations has proved its effectiveness.

In many cases, especially if the attack has lasted more than forty-eight hours, it is impossible to lower the tension with pilocarpine or any other miotic. In these cases, operation must be under-

taken for only forty-eight hours and remain totally and permanently blind, in spite of complete relief of the tension. To be sure, most eyes can tolerate a high tension considerably longer than this and still recover part or all the vision if the tension is promptly lowered. However, there is no way of knowing which eyes can tolerate high tension and which cannot. One must act promptly, on the assumption that all eyes are vulnerable to high tension.

I have said that it is always advisable, if possible, to lower the tension with miotics before undertaking surgery. There are two points that deserve emphasis. The first concerns the type of drops used and the frequency of their administration. To prescribe 1 per cent pilocarpine three times a day for an eye in an acute attack of glaucoma is like throwing a straw to a drowning man, and about as effective. One should use 4 per cent pilocarpine or 1 per cent eserine, or one of the newer, more powerful miotics, such as Mecholyl and Prostigmine. The drops should be instilled every fifteen minutes for two or three hours, and at least every hour thereafter day and night until the tension is lowered to normal. The

second point in the use of drops is that they must not be relied on too long. A period of twelve hours may be considered an adequate trial. If after this time there is not a substantial lowering of the tension, surgery must be undertaken at once. In patients first seen several days after the onset of the attack, even twelve hours is too long to wait before operation is undertaken.

Chronic glaucoma constitutes no such emergency. Here there is plenty of time carefully to consider the pros and cons of various forms of treatment. The choice of treatment comprises the continued use of a miotic or operation, or both. There is no disease of the eye that calls for such sound clinical judgment concerning correct treatment, as chronic glaucoma does. It is not enough to make the diagnosis and prescribe eye drops to be used two or three times a day. One must be sure that the drops employed bring the tension to, and maintain it at, a sufficiently low level to prevent further damage to the eye. Only when a glaucomatous eye has been observed for some time can one surely say what is the normal tension for *this particular eye*. Some eyes tolerate a pressure up to 30 mm. of mercury without damage, whereas others will show progressive field loss with the pressure maintained at 20 to 25 mm.

In the management of chronic glaucoma, an accurate yardstick with which to measure the effectiveness of treatment is the study of the visual field. No patient suffering from chronic glaucoma is well treated unless periodic measurements of the visual field are made. If loss of visual field continues, treatment, whether it be medical or surgical, has been inadequate. In such cases, whatever the level of the tension, it is too high for this particular eye. The treatment must be revised, or total blindness in the eye will result.

I shall not attempt to discuss the indications for operation in chronic glaucoma. Suffice it to say that the younger the patient the stronger the indication for operation. I believe that most patients under the age of sixty who are in good health and have a normal life expectancy should have operation. Even the most faithful use of drops often fails to hold the disease in check over a period of years. However, each case must be decided on its own merits, and no fixed rules can be laid down. It is not an easy thing for the ophthalmologist to advise surgery on a symptom-free, normally seeing eye. An operation successful in lowering the intraocular pressure may not only fail to improve the vision but may actually lessen it. There is no dramatic restoration of vision here as in the extraction of a cataract. Yet,

if one undertakes to treat the disease at all, one must not hesitate to treat it properly.

#### PREVENTION OF BLINDNESS

General practitioners are often the first to see the patient with acute glaucoma. In every case of severe nausea and vomiting, especially when accompanied by pain in the eye or headache, they should consider this possibility. The patient may be so sick as to forget about the eye and complain only of nausea, vomiting and general prostration. In the early stages, congestion of the eye may be very slight, and may easily escape attention if it is not looked for especially. If there is the slightest doubt whether the case is one of acute iritis or acute glaucoma, it is best not to give any treatment at all. In an attack of acute glaucoma, one drop of atropine may mean the ruin of an eye, for the effect of the atropine is not only deleterious but cannot be overcome by miotics. When the diagnosis has been made, it is the attending physician's responsibility to see that there is no delay in the institution of treatment. The patient may be prostrated by the disease, but he is never too sick to be moved to a place where proper treatment can be carried out. He will never get better until the tension is lowered.

In chronic glaucoma, the physician is not often called on to make the diagnosis. Yet many physicians discover glaucomatous cupping of the disk in routine ophthalmoscopic examination. When the patient has a visual complaint, he should be referred to a physician qualified to diagnose and treat any disease of the eye. The patient should not be permitted to disregard ocular pain, blurred vision, seeing colored rings around lights, poor vision in dim light and slow adaptation to darkness. When a patient who complains of loss of vision is referred to the ophthalmologist, the physician is entitled to an adequate explanation of this symptom. When the diagnosis of chronic glaucoma is made, one can be of considerable help to the ophthalmologist by urging that the patient faithfully carry out the treatment recommended. The patient should be urged to report for the periodic check-ups that are so important in the treatment of this disease. The physician can help more than a little in getting the patient adjusted to the situation: his advice is invaluable in helping the patient to avoid the stresses and strains of life, particularly the emotional strains, which have such a distinctly unfavorable influence on the disease. I may say in passing that glaucoma bears no known relation to any constitutional disease.

Patients past middle life should have a thorough

check up of their eyes at least once every two or three years. Most cases of chronic glaucoma are discovered in just such routine examinations. A check up once a year in older people is not too frequent. It makes no difference if they are known to have partial loss of sight from retinal disease or incipient cataract. Glaucoma can coexist with any disease of the eye. The most tragic situation has many times arisen in cases when both incipient cataract and glaucoma are present. The patient may be advised of the presence of the cataract and may watch his vision slowly fail, expecting when he is entirely blind to have his vision restored by cataract extraction. One often has to tell such patients that, true enough, a partial or complete cataract is present, but that all vision has been irretrievably lost from glaucoma. Vision lost from chronic glaucoma can never be restored. One should therefore do everything possible to prevent blindness from this disease.

5 Bay State Road

#### DISCUSSION

DR. CHARLES F. NUTTER (Nashua). There is much to learn about glaucoma. Dr. Chandler's exposition of this subject was very clear, but perhaps some of the things he said are not clear to those who are not particularly interested in the disease. Great stress has been properly laid on the increased hardness of the eye. There is pressure on the nerve, which is the weak part of the wall, of course.

Although some ophthalmologists may disagree with me, I have seen cases in which the tension was reduced to

normal, but in which progressive blindness occurred, so that later on, the eye was of no use. In those cases, one may be able to find some reason for it. But I believe that some element is present with which we are not really familiar.

Dr. Chandler spoke of the danger of one dose of atropine. I remember a case in which a physician was called to see a patient who had a bilious colic. The pain was not referred to the head; it was underneath the right shoulder blade, extending down into the region of the gall bladder, with every symptom of the passing of gallstones. The patient was given large amounts of morphine and atropine. The next morning, he was totally blind, and remained so, despite all treatment. If you want to give morphine, all right, but leave the atropine out.

One other thing that is very important is the early recognition of glaucoma. I believe that many cases are frequently overlooked, even by ophthalmologists. Consider the large percentage of patients who are wearing glasses, cases of blurring; some of them are at least temporarily blind, and they keep going back to the optometrists or someone who is not legally qualified to make diagnoses. Consequently, many cases of glaucoma get ahead of us. I think that when receiving a prescription for glasses, all patients should be seen by someone who is able to understand and recognize the symptoms of a case of chronic glaucoma.

DR. CHANDLER (closing). It is true, as Dr. Nutter said that we, as ophthalmologists, have a long way to go before we know the answer to glaucoma. Yet the fact is that although we fail in a certain number of cases, there is no excuse for the conception in the mind of the average layman that glaucoma means blindness. I think it is fair to say that in the vast majority of cases, if the diagnosis is made reasonably early, and if the condition is properly treated, the patient with this disease may have useful vision so long as he lives.

## MEDICAL PROGRESS

### SURGICAL CARE AND OPERATIVE TECHNIC\*

JOHN D. STEWART, M.D.†

BUFFALO, NEW YORK

THE current general surgical literature continues to attest to the diversity of modern surgical interests. Much attention is given to such major topics as nutrition, sulfonamide therapy of infections and wound healing. Increased interest in shock and problems of trauma is seen as an inevitable concomitant of war; this was also true in World War I.

#### NUTRITION

Continued advance in the understanding of the relation between nutritional deficiencies and post-operative complications is evident. As the pre-operative condition of the patient is studied more generally and with improved methods, two facts stand out—that nutritional deficiencies are frequently multiple, and that they are often present in latent or subclinical form.<sup>1</sup> Thus, it may happen that unsuspected borderline vitamin or protein deficiency is intensified by the stress of the surgical ordeal and the postoperative period of starvation, with resultant grave complications. The postoperative bleeding of prothrombin deficiency, delayed wound healing or wound dehiscence, malfunction of a gastroenterostomy stoma, postoperative psychosis and liver failure may be taken as illustrative examples.

The importance of the plasma proteins in surgical problems is discussed by Ravdin,<sup>2</sup> who states that it is not only the measurable concentration of the plasma protein that is significant, but also the amount of the reserve or storage protein. Madden and Whipple<sup>3</sup> present the concept of dynamic equilibrium between the body protein stored as a reserve against adversity and the nitrogenous elements in active metabolism. If the exogenous supply of protein is suddenly cut off, the immediate consequences depend on the state of the available reserves. These authors believe that new plasma protein probably flows largely from the liver, although some globulins may be formed elsewhere.

Hartzell, Winfield and Irvin<sup>4</sup> describe their

\*All articles in this series will be published in book form: the current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

†From the University of Buffalo School of Medicine and the Edward J. Meyer Memorial Hospital.

‡Professor of surgery, University of Buffalo School of Medicine; surgeon-in-chief, Meyer Memorial Hospital.

findings in a study of biochemical changes in the plasma of 20 patients at the time of dehiscence of laparotomy wounds. In 14 with dehiscence of clean wounds, the average plasma vitamin C concentration was 0.36 mg. and the serum-protein concentration 5.83 gm. per 100 cc., and the albumin-globulin ratio 1.25; in 6 patients with dehiscence of infected wounds, the respective values were 0.38 mg., 5.84 gm. and 1.30. Average normal values in a group of 20 medical students were found to be 0.96 mg. per 100 cc. for plasma vitamin C and 7.19 gm. per 100 cc. for serum-protein concentration. The authors emphasize the value of correcting deficiency of vitamin C and plasma protein before operation.

In the treatment of hypoproteinemia in surgical patients, Casten and Bodenheimer<sup>5</sup> report that in their experience the administration of massive transfusions of plasma provokes the greatest and most sustained rise in serum proteins. They point out that since the liver holds the key position in maintaining normal stores of plasma protein, all the measures known to favor liver function should be taken, including the administration of carbohydrate, protein and vitamins in adequate amounts. Elman<sup>6</sup> discusses the usefulness of intravenous aminoacid infusions in the correction of protein deficiency. The title of his paper, "Parenteral Replacement of Protein with Amino-Acids of Hydrolyzed Casein," is not free from Hibernicism, since aminoacids cannot substitute for body protein directly, but become protein only through synthetic cellular activity. The usefulness of aminoacid mixtures obtained by enzymatic hydrolysis of casein in the maintenance of nitrogen balance when administered intravenously is receiving confirmation in a number of clinics. In my experience, such therapy is effective even in the presence of severe liver damage.

The occurrence of prothrombin deficiency as a complication of perforative appendicitis and manifested by massive hemorrhages from the operative wound has been reported.<sup>7</sup> It is recommended that in the management of peritoneal sepsis, particularly if it is of gastrointestinal origin, the plasma prothrombin value be determined at frequent intervals and vitamin K be given parenterally if needed. Hypoprothrombinemic bleeding

may take place in these cases even in the absence of signs of toxic hepatitis and hepatic impairment.

### HEPARIN

Clinical experience is accumulating by which the proper place of this anticoagulant can be estimated. Murray<sup>8</sup> lists the indications for heparinization as follows: arterial suture, excision or repair of arteriovenous fistula, venous grafting, embolectomy and mesenteric thrombosis. In addition, he reports that the prolonged morbidity, discomfort and disability following thrombophlebitis and phlebothrombosis can be reduced by the administration of heparin for four to eight days, as shown in experiences with over 125 patients. He has encountered no cases of pulmonary embolism attributable to the use of heparin, and he rightly points out that heparin has no effect on the established clot. In considering the disadvantages of heparinization, to the drawback Murray mentions—the necessity for immobilizing the patient while he is receiving a constant infusion—may be added the expense, the difficulty in maintaining even and moderate delay in clotting, and the need for frequent determinations of clotting time. Possible interference with inflammatory fixation of bacteria is also to be kept in mind.

Some of the disadvantages of heparin in the maintenance of delayed coagulability in patients may be obviated if further clinical trial supports preliminary observations on the use of a coumarin derivative isolated by Link et al.,<sup>9</sup> of the University of Wisconsin. This substance has recently been identified as the chemical element responsible for the impairment of clotting seen in cattle suffering from the effects of eating spoiled sweet clover. When taken by mouth, the drug inhibits clotting over a period of several days, apparently without other ill effects.

Lehman and Boys<sup>10</sup> report interesting experimental results in the use of heparin in preventing peritoneal adhesions. Their work has been done entirely on animals and does not as yet permit clinical application. They summarize their observations as follows: intraperitoneal heparinization in three daily doses of at least 1000 units largely prevents the re-formation of divided peritoneal adhesions in the dog; hemorrhage following the intraperitoneal administration of heparin is not a danger if hemostasis is complete before the heparin is administered; and contamination of the peritoneum does not appear to be a contraindication to the intraperitoneal use of heparin.

### OPERATING-ROOM INFECTIONS

Continued interest is shown in reducing infection of clean surgical wounds as near as possible

to the ideal zero. In a study<sup>11</sup> of the condition of the wound after 606 clean operations, infection of some degree was found in 3.81 per cent, whereas in 1.59 per cent infection was sufficiently severe to prolong the patient's stay in the hospital or endanger life. These figures are probably indicative of the incidence in the average well-run surgical service. Since efforts at further improvement in surgical technic must be directed at the occasional poor result, the challenge here is evident. Hart<sup>12</sup> reports on further experiences with the method he has devised for sterilization of the air in the operating room by bactericidal radiation. He has encountered no untoward results beyond an occasional erythema in members of the operating team who neglected the proper covering. Hart considers the technic to be practical, safe and effective, and states that a significant reduction in wound infection has resulted from its use in his clinic. It should be noted, however, that the method has yet to win approval elsewhere. Rice, Weed and Raidt<sup>13</sup> point out that satisfactory investigation of the bacterial content of the operating-room air can be done only with the air centrifuge of Wells, for the Petri dish method gives misleading results.

Two excellent studies have been reported during the past year on the effectiveness of surgical masking. Hirshfeld and Laube<sup>14</sup> have devised a method for testing masks under conditions of actual use, involving measurements with the Wells air centrifuge. Their most significant conclusion is to the effect that masking of the operating team would be unnecessary if no one talked. They find that the direct spray contamination of talking is greatly reduced when a mask is worn but is still higher than that of quiet breathing without a mask. As tested by their method, the usual four-ply or six-ply gauze mask is grossly inadequate, especially after it has been worn for a while. Rooks, Cralley and Barnes<sup>15</sup> have investigated the value of various types of hospital masks with respect to bacterial filtering efficiency and resistance to air flow. They point out that a completely impervious mask has no value, merely serving as a deflector of the organisms, whereas a highly porous, and hence comfortable, material may have poor filtering power. They find that repeated laundering of masks improves filtering efficiency without proportionate increase in resistance to the breath.

### SUTURE MATERIAL AND WOUND HEALING

Judging from the number of reports in the current literature on the use of other suture materials, one would suppose that surgeons are highly dissatisfied with catgut and silk. No less than nine

papers are at hand dealing with the subject. Alloy steel wire has acquired a considerable measure of esteem since its introduction by Babcock in 1932. Jones, Newell and Brubaker<sup>16</sup> state that the substitution of steel wire for catgut has resulted in lowering of the incidence of wound disruption following operations on the biliary tree from 11.0 to 1.2 per cent, whereas the incidence of infection in abdominal wounds after combined abdominoperineal resection and midline colostomy has fallen from 27.5 to 0.85 per cent. They use a series of buried figure-of-eight wire sutures for the peritoneum and rectus sheath, and dispense with stay sutures. In a study by Preston<sup>17</sup> of the tensile strength of skin wounds in white rats sutured with annealed stainless steel wire and with other suture material, the wounds closed with wire had greater strength and showed less local reaction. This author points out that the surgeons' gloves may be torn by the wire ends and that injury to the surgeons' hands in an infected field may occur. Careful technic is essential in using the wire.

Holman and Eckel<sup>18</sup> advocate the use of 20-gauge silver-wire stay sutures in laparotomy wounds. All layers are included, and the separate layers are united with No. 0 chromic catgut. The wire through-and-through sutures are removed in fourteen to sixteen days if no infection is present.

Further experience with the use of cotton thread for suture material tends to confirm original impressions concerning the validity of the technic. Localio and Hinton,<sup>19</sup> on the basis of personal observations, discuss the manner of using cotton thread and the most satisfactory grades and brands. They recommend that cotton thread be sterilized by boiling from ten to twenty minutes and used while wet, for its tensile strength diminishes on drying.

Enthusiastic reports are at hand on the experimental and clinical results of the use of synthetic plastic fiber as buried sutures. According to Aries,<sup>20</sup> Nylon sutures are well tolerated by tendons and nerves, and do not evoke a leukocytic or even lymphocytic response. In infected wounds, Nylon acts much the same as silk in holding the tissues securely and remaining unchanged, and the author concludes that Nylon has all the good qualities of silk and in addition is stronger and less irritating. It may be boiled several times without losing its original strength. Aries recommends a multifilament rather than a monolithic Nylon thread, for although the former evokes slightly more local reaction, it is far easier to handle and the knots are safer and less bulky. Bellas,<sup>21</sup> after using a synthetic plastic-suture ma-

terial in over 600 wounds, is similarly enthusiastic. In work on guinea pigs and dogs, he finds that remarkably little local reaction is produced by this suture material.

In a careful and well-planned study of factors influencing the tensile strength of healing skin wounds in animals, Botsford<sup>22</sup> finds extracts of spleen and other tissues of no value in accelerating healing. He describes experiments showing the value of secondary suture of wounds, in support of accepted clinical practice. The superiority of silk over catgut is apparent in these investigations, according to the author. In establishing the normal curve of tensile strength of healing skin wounds in guinea pigs and dogs, Botsford notes considerable variation in the ability to heal among supposedly healthy animals and in the individual animal with multiple wounds; these matters should be kept in mind in any consideration of the question of wound healing.

#### SURGICAL OPERATIONS

Wangensteen<sup>23</sup> vigorously champions aseptic anastomosis in gastrointestinal resections, and presents his experience with the closed method of anastomosis in 100 cases, comprising 83 gastric resections, 14 colonic resections and 3 miscellaneous cases. Only 1 case of postoperative gastric hemorrhage was encountered in the gastric resections, and the author attributes this to the use of the Hofmeister plan of anastomosis, whereby the more vascular part of the stomach is turned in, to ligation of visible subserosal vessels, to the use of a crushing clamp on the stomach and to the use of a coagulating current of the diathermy machine. The author admits that the closed anastomosis results in turning in a wider cuff of poorly approximated visceral wall, but points out that the commonly used Connell stitch is not free from this fault; he apparently does not consider this objection important. The report also includes an exhaustive discussion of details of preoperative and postoperative care. Wangenstein employs a bedside weighing scale in determining the state of hydration of poor-risk patients, a maneuver worthy of wide attention. He uses suction on a forked-type nasogastric catheter to prevent distention of the proximal jejunal loop after gastrojejunal anastomosis, the catheter being manipulated into the ascending and descending jejunal limbs at operation. He concludes that obstruction of the afferent loop in gastrojejunal anastomosis, without gangrene, is a neglected but significant cause of death after gastric resection.

Hoag and Saunders<sup>24</sup> consider the causes of obstruction following gastroenterostomy and sub-

total gastric resection, and propose jejunoplasty as a corrective operation. The procedure embodies the principle of the Finney pyloroplasty on the two limbs of the jejunum at the site of anastomosis, and the incision may be extended to the gastric wall in cases of contracted gastric stomach or marginal ulcer, according to the authors. Although most experienced surgeons have probably resorted to this procedure at one time or another, it is not to be considered the treatment of choice, as Allen notes in his discussion of the presentation. Possible jejunal necrosis and marginal ulceration, as well as the need for considerable operative manipulation in what may be a field of adhesions and inflammation and in what may be a depleted patient, are factors that weigh against routine adoption of jejunoplasty in this connection.

The rapidity of severe depletion in the presence of malfunctioning gastroenterostomy is stressed by Allen and Welch<sup>25</sup> in a comprehensive discussion of this problem. They advise early performance of jejunostomy in the treatment of the condition. The laparotomy wound is reopened for this purpose, and a simple purse-string type of jejunostomy is performed, the catheter being brought out through a stab wound. Provided the nutrition of the patient can be kept in satisfactory state, as by supplying a generous and complete dietary mixture through the jejunostomy tube, their figures show that spontaneous relief of the obstruction can usually be expected.

The use of a vitallium tube in the reconstruction of a strictured common duct is described by Pearse<sup>26</sup>. The tube is flanged, and the ends are flared slightly to fix it permanently in place. Since vitallium is notable for strength, lack of electrolysis and lack of local irritating effects, its superiority over the rubber catheter usually employed for common duct restoration may establish its place in this connection. As the author hastens to add, the value of such a vitallium tube is problematic if a gap is to be bridged between the ends of the duct.

McKittrick and Warren<sup>27</sup> describe a technical measure that has proved extremely helpful in their experience. As a preliminary to subtotal colectomy and other procedures requiring wide intraperitoneal exposure, the Miller-Abbott tube is passed. The small intestine is thus deflated and threaded on the tube beforehand, and at the operation not only is exposure of the operative field simplified, but the trauma involved in walling off loops of small intestine is obviated.

A point of concern to those interested in the surgery of the biliary tree is dealt with by Brunschwig and Clark.<sup>28</sup> In a case in which resec-

tion of the common duct for cancer was being performed, the main hepatic artery was found involved in the growth and had to be ligated and resected. Death of the patient ensued twenty-two days later, from what was thought to be liver failure. At autopsy, there was infarction of the right lobe of the liver, with no peritonitis and no pancreatitis. The authors report that Alessandri in 1937 was able to collect from the literature 10 cases of ligation of the hepatic artery in man, with fatal results in 6 and recovery in 4. He found also that in 18 reported cases in which one of the principal branches of the hepatic artery was ligated, lobar necrosis and early fatality resulted in 7. In man, recovery from ligation of the hepatic artery or its right or left branch apparently depends on the extent of collateral circulation present in the patient.

#### CARCINOMA OF THE AMPULLA OF VATER

This difficult surgical problem is now being attacked with a measure of success, made possible by advances in knowledge of the preoperative needs of the jaundiced patients.<sup>29</sup> Orr<sup>30</sup> reviews the 14 reported cases of resection of the duodenum and head of the pancreas for carcinoma of the ampulla, and adds a case of his own to the group. Five of the fifteen patients died after operation without leaving the hospital, and 3 died of metastases, 2 from stenosis of the cholecystgastrostomy stoma, and 1 from bile peritonitis. Four patients were still alive at the time of the report. Although disheartening, these results demonstrate the technical feasibility of excising the lesion, and will undoubtedly pave the way for more successful experiences. The best plan of surgical attack requires further study, bearing on such questions as the choice between one-stage and two stage procedures, and the optimal type of anastomosis between the obstructed biliary system and the gastrointestinal tract.

Moreland and Freeman<sup>31</sup> point out that two serious complications may follow resection of carcinoma of the ampulla of Vater—fatty degeneration of the liver and cholangitis. The evidence indicates that loss of the external pancreatic secretion can be successfully dealt with by such measures as a low fat diet and administration of lipocaine, pancreatic tissue or choline. These authors state that a high percentage of tumors in this region are of low grade malignancy. Occasionally, the growth involving the ampulla is sufficiently localized to permit transduodenal excision, although this method carries with it the danger of inadequate removal of tissue and is therefore not acceptable to surgeons experienced in the treat-

ment of cancer. River, McNealy and Ragins<sup>32</sup> report 3 cases of successful transduodenal excision of periampullary carcinoma, with reimplantation of the common and pancreatic ducts. Two of the patients developed stenosis of the common duct and required subsequent internal biliary drainage. The authors rightly stress the need for carefully determining the condition of the ampulla in operating on any patient with obstructive jaundice, so that no early ampullary growth will be overlooked.

#### POSTOPERATIVE PULMONARY COMPLICATIONS

Aspiration bronchopneumonia of varying severity is far commoner after surgical operations than is generally realized, according to Irons and Apfelbach.<sup>34</sup> In fatal cases, the true diagnosis is often missed because of failure to culture lung tissue, tracheal and stomach contents and blood. The characteristic alterations in the pulmonary parenchyma are most readily recognizable if the necropsy is performed within an hour or two of death. Their warning to the surgeon and anesthesiologist is timely, and points to the need—especially in upper abdominal operations—of preliminary evacuation of the stomach by intubation and maintenance of the head and thorax in a measure of dependency during the operation. In the prevention of postoperative pulmonary complications, Gordon<sup>34</sup> stresses the value of postoperative bronchial drainage by cough, posture or bronchoscopy. He regards bronchoscopy as a safe and simple procedure in well-trained hands, and advises early use of the measure in the treatment of postoperative pulmonary atelectasis.

Lindskog<sup>35</sup> presents clinical and experimental evidence bearing on the etiology of postoperative pulmonary complications. He states that bronchitis, atelectasis and pneumonitis continue to be a source of considerable morbidity and a cause of high mortality, especially in upper abdominal surgery. Lindskog finds that general anesthesia (Avertin) results in an immediate reduction in pulmonary subtidal volume by about 20 per cent before operation. A similar immediate reduction in subtidal volume was observed as a result of operation under local procaine anesthesia with preliminary morphine sedation. His studies led him to postulate a humoral theory for the etiology of postoperative pulmonary complications, according to which histaminelike substances are liberated from the sites of operation; these substances provoke secretion and bronchoconstriction in the lung. The stage is thus set for the action of mechanical factors that increase respiratory embarrassment.

#### POSTOPERATIVE CARE AND HOSPITALIZATION

Boyd<sup>36</sup> discusses the formation of renal calculi in bedridden patients, and reports 4 cases in which calcium phosphate stones formed rapidly and required surgical removal. One of the patients was being treated for delayed union of a fractured femur. Measures recommended in the prevention of such stones include acid-ash diet, avoidance of alkali, maintenance of large urine volume and frequent change of position in bed, with emphasis on assuming the prone position when possible.

A recent paper by Leithauser and Bergo<sup>37</sup> reminds me of a remark that the late Dr. E. Amory Codman once made to me on the subject of appendicitis. He predicted that the day would come when interval and prophylactic appendectomy would be performed through a McBurney incision under local procaine anesthesia in the surgeon's office, and the patient would be allowed to go home a few hours later. Leithauser and Bergo discuss their results in a group of 370 cases of appendectomy, in which early rising and ambulatory activity were practiced. The operation was for acute (nonperforative) and chronic appendicitis, and the average period of confinement to bed after operation was 1.5 days. The patients left the hospital by automobile and usually returned on the sixth day for the first dressing. In 66 laparotomies for other conditions, the average time of confinement to bed after operation was 1.9 days; in 18 cholecystectomies, the patients averaged 1.5 days in bed and 8.3 days in the hospital. In the entire group of 436 cases of laparotomy, no wound dehiscence, hernia, pneumonia, thrombophlebitis or other serious complications were observed (except hemorrhage in a gastrojejunal ulcer). The authors used the McBurney incision for appendectomy, and an oblique or transverse incision for cholecystectomy, the wound closure being made with chromic catgut and interrupted, buried steel-wire sutures for the fascia. Their "clinical results suggest the possibility that certain pathologic reflexes originating from the area of mechanical and chemical injury impair respiration and initiate a delay in peripheral circulation which leads to postoperative complications, and that strict confinement to bed favors the development of such complications."

Although few surgeons would care to adopt this program at present, even if it were acceptable to their patients, it must be admitted that the length of confinement to bed and hospital after operation is determined oftener by tradition than by criteria based on careful clinical research. Fur-

ther evidence on this important question should be obtained by studies in a number of clinics

### CASE 27421

#### PRESENTATION OF CASE

*First Admission.* A twenty-month old Italian girl was admitted to the hospital for study.

The child was born at term, weighed 9 pounds, was breast fed for one year, with supplementary feedings after four months, and had been given unspecified amounts of orange juice. She had been well except for occasional coughs and colds until three months before admission, when pallor was noticed. Furthermore, the patient became restless and cried easily, and two weeks before admission, fever and indefinite pains in the hands and stomach were noticed. There had been no vomiting or diarrhea.

The family history was noncontributory. Neither of her two siblings was anemic.

On examination, the patient was well developed but flabby, with puffiness of the hands and feet, and pale, yellow skin. The scleras and mucous membranes were also very pale. The tonsils were large and cryptic; there was no lymphadenopathy. The lungs and the heart were normal except for a soft systolic murmur at the third left interspace. The abdomen was full; the liver was palpable 4 cm. below and the spleen 1.5 cm. below the costal margin. The extremities showed moderate enlargement of the epiphyses.

The urine on numerous occasions showed a + test for albumin and many white blood cells per high-power field. The red-cell count was 1,920,000 with a hemoglobin of 30 per cent, and the white-cell count 21,000 with 54 per cent polymorphonuclears, 36 per cent lymphocytes, 1 per cent monocytes, 7 per cent transitional cells, 21 per cent reticulocytes and 23 per cent nucleated red cells. Smears showed achromia, marked variation in size and shape, and many microcytes and macrocytes. The stools were guaiac negative.

The patient was given a high vegetable and fruit diet with 0.1 gm. of iron citrate each day. The hemoglobin rose to 50 per cent, and the red-cell count to 3,000,000, the smear remaining unchanged. The temperature on one occasion went to 105°F., and this was variously attributed to pyelitis and acute suppurative otitis media. The

patient was discharged three and a half weeks after admission.

*Final Admission* (eighteen years later). In the interval, the patient had been admitted to this and other hospitals on nine occasions, in addition to innumerable visits to the Out Patient Department.

A few months after discharge, the patient was seen again at this hospital, and a diagnosis of lymphatic leukemia made and x-ray treatment given. A year later, she was admitted to another hospital, where an enlarged liver and greatly enlarged spleen were noted, and a von Jaksch's syndrome diagnosed. In a few weeks, the patient was readmitted to that hospital with a temperature of 100°F.; an x-ray film of the chest suggested tuberculosis, and a von Pirquet test was positive. At another institution, the blood was reported to show a red-cell count of 4,180,000 with a hemoglobin of 60 per cent, and a white-cell count of 19,400, with 264,000 platelets and 19 per cent reticulocytes.

At the age of four, the patient had suffered from whooping cough, epistaxis and, later, bronchitis. The following year, a severe epistaxis ("a half cupful") occurred, followed by pain and swelling in both ankles lasting three days. At the last-mentioned hospital, a fragility test showed hemolysis beginning at 0.32 per cent and complete at 0.14 per cent, and an x-ray film of the chest showed the heart and supracardiac shadow to be increased in width. Treatment consisted of 1200 erythema skin units of x-ray.

At six years, the patient was said to have had lobar pneumonia and later during this year was seen at the same hospital complaining of cough and epistaxes of three weeks' duration. On examination she was well developed and nourished, but pale, with the spleen 6 cm. below the costal margin. The red-cell count was 3,700,000 with a hemoglobin of 53 per cent; the white-cell count was 26,500, and the smear as before. Two years later, she developed a prostrating cold and definite scleral icterus, with the liver 4 cm. below the costal margin; the blood picture, however, was slightly improved. At ten years, the icteric index was 20, and a Graham test was negative; some time later, the blood picture was noted to be essentially unchanged. During this period, the patient again contracted lobar pneumonia, and at the age of twelve was readmitted to this hospital complaining of a severe cold and pains in the abdomen and back, of four days' duration. The temperature was 103.6°F., and there were signs of consolidation at the left lung base. A fragility test showed hemolysis between 0.32 and 0.20 per cent. The spleen was not palpable, but following

recovery from the acute infection, both the spleen and the gall bladder, which contained stones, were removed. The spleen weighed 97 gm. and presented an unusual picture. Scattered throughout were numerous foci containing laminated deposits of brownish material, which stained for iron. These were largely enclosed by surrounding fibrous tissue and often showed foreign-body giant cells in contact with these deposits. Extending from these areas, strands of fibrous tissue stretched out and occasionally formed confluent areas of fibrous tissue. There was some increase of the perivascular fibrous tissue, but more marked increase of the perivascular elastic tissue. There was little if any intimal thickening. The lymphoid tissue was markedly reduced, and there was well marked congestion. Subsequently, a tonsillectomy was performed. The patient was discharged, the blood picture being unimproved.

It had previously been observed that occasional crises occurred during which the patient became more icteric, and the white cell count and hemoglobin fell to lower levels. She was readmitted to this hospital the same year in one of these crises and complained of headache and fever of five days duration. On examination, the temperature was 100°F, and the scleras icteric; dental caries were noted, and keloids had developed in the operative scars. The blood showed a red cell count of 1,900,000 with a hemoglobin of 45 per cent, and a white cell count of 14,600 with a normal differential. The red cells were as before, with 4 per cent reticulocytes and a large number of normoblasts. Gradually, the blood returned to its old level and did not change over the next two years, despite large doses of iron.

At fourteen, the patient suffered an acute febrile attack accompanied by pain and tenderness in all her joints. This lasted one month, and examination subsequently showed cardiac enlargement, with a continuous thrill in the neck and a continuous murmur in the right second interspace. Both the thrill and the murmur disappeared in dorsal decubitus. A rheumatic nodule was said to have been found in one foot.

For the next five years, the patient remained fairly well and even did light work. One year before her final entry, she was readmitted to this hospital with her stereotyped complaints of fever, cough without sputum and pain in the "stomach." The temperature was 104.6°F, and physical examination suggested right lower lobe pneumonia. An x-ray film showed evidence of consolidation at the right base, and the heart was still slightly enlarged. The red-cell count was 2,570,000, the hemoglobin 7.5 gm, the hematocrit 18 per cent,

the color index 0.9, the mean corpuscular volume 63 cu. microns and the mean corpuscular hemoglobin 26 microgm. Hemolysis began at 0.34 per cent and was complete at 0.14 per cent, control figures running 0.42 and 0.30 per cent, respectively. A sternal biopsy showed erythrogenic hyperplasia, with normoblasts predominating. The patient made a quick recovery on sulfapyridine, but three months later she was readmitted with exactly the same picture, even to the same lobe. The roentgenologist doubted the presence of pneumonia, but a blood culture yielded a Type 4 pneumococcus. The patient again recovered, and following discharge took a course of antipneumococcus vaccine and a course of liver extract injections. X-ray films of the hands and skull and also those of her sister showed no evidence of erythroblastic anemia.

The patient was finally admitted at the age of twenty, complaining of fever and pallor.

On examination, she was slightly obese and did not appear ill. The skin and scleras were slightly icteric. The heart and lungs were normal, except for fine rales and diminished breath sounds over the right base. The abdomen was normal.

The temperature was 105.8°F, the pulse 120, and the respirations 24.

The urine showed a specific gravity of 1.012, with a ++ test for albumin, and the sediment contained an occasional white blood cell and granular cast per high-power field. The blood showed a red cell count of 3,300,000 (260,000 of which were sickle cell forms) with a hemoglobin of 60 per cent, and a white cell count of 19,300 with 67 per cent polymorphonuclears, 23 per cent lymphocytes, 2 per cent normoblasts and 5 per cent myeloblasts. The serum van den Bergh and blood cholesterol, protein, nonprotein nitrogen and chloride were all normal, and two blood cultures were negative.

X-ray films of the chest showed no evidence of consolidation. There was a widening of the lower dorsal vertebrae that was suggestive of an old epiphysitis. Serial films, however, showed the development and progression of an unusual type of pneumonia involving first the left and then both lungs.

The patient was given sulfapyridine, then sulfathiazole, and while she was still on the drug, the temperature rose to 105°F, where it remained for some time. The apex impulse was heaving, and there were runs of bigeminy and trigeminy. An electrocardiogram showed a PR interval of 0.21 second. One observer noted cardiac enlargement and a systolic and a slight apical mid diastolic murmur, with accentuation of the pulmonic second sound. The right knee became swollen, the right

thumb painful. Finally, dyspnea became more and more severe, and the patient was placed in an oxygen tent. The temperature rose to 106°F., rales developed throughout both lungs, and a pleural friction rub was heard.

Death occurred one month after admission.

DIFFERENTIAL DIAGNOSIS

DR. THOMAS HALE HAM<sup>4</sup>: In summary this is a striking report of an Italian girl who was observed almost every year up to the age of twenty years, when she died apparently from pulmonary disease, which complicated a hemolytic anemia. The features of her clinical course were as follows. She had multiple episodes of hemolytic anemia associated with joint pains or pains in the

when removed at operation. The liver was moderately enlarged at all times.

The finding of sickle cells, together with the above evidence, confirms the diagnosis of sickle-cell anemia to explain the blood dyscrasia. Without the pathognomonic observation of sickle-shaped red cells, however, the following types of anemia would require differentiation: sickle-cell, erythroblastic (Cooley's), chronic hypochromic and familial microcytic. Certain distinguishing features<sup>1</sup> of these diseases are shown in Table 1. It is evident that hypochromic and familial microcytic anemia can be excluded because of the presence in this patient of jaundice, splenomegaly, increased reticulocytes and nucleated red blood cells. The distinction between Cooley's anemia and

TABLE 1. Distinguishing Features of Several Types of Microcytic Anemia.

FEATURE	SICKLE-CELL	ERYTHROBLASTIC (COOLEY'S)	CHRONIC HYPOCHROMIC	FAMILIAL MICROCYTIC
Inheritance of trait	Dominant	Recessive	None	Dominant
Predominant race or nationality	Negro predominately Mediterranean (Italian) occasionally.	Mediterranean	None	Mediterranean
Morphology of red blood cells	Sickled forms, increased reticulated and nucleated red cells, microcytosis and marked variation in size and shape.	Increased reticulated and nucleated red cells; microcytosis and extreme variation in size and shape	Less than 5 per cent reticulocytes; microcytosis and moderate to extreme variation in size and shape.	Less than 5 per cent reticulocytes; microcytosis and marked variation in size and shape.
Maximum resistance of red blood cells to hypotonic saline solution	Increased	Increased	Increased	Increased
Icteric index	Frequently elevated	Frequently elevated	Normal	Normal
Splenomegaly	Frequent	Usual	Rare	None
Bone changes	Occasional	Usual	None	Slight changes in skull

stomach and frequently with cough and fever. Coincident with several attacks of anemia, she had pulmonary complaints and signs interpreted usually as pneumonia. The laboratory observations revealed an anemia that developed rapidly on numerous occasions and reached a level of 1,900,000 red cells on one occasion. Sickle cells were demonstrated in the blood on her last hospital admission. An increased number of reticulated and nucleated red cells were always present during severe anemia. The red cells were microcytic, with marked variation in size and shape, and showed increased resistance to hemolysis in hypotonic solutions of sodium chloride. Icterus was observed clinically three times, and on one occasion the icteric index was 20. The leukocyte count was consistently elevated. The spleen increased in size from a few centimeters to 6 cm. below the costal margin. Subsequently, it disappeared clinically, and weighed only 97 gm.

sickle-cell anemia in this case is possible only by the observation of the sickle cells. Otherwise, it might be impossible to differentiate these two diseases, especially since the patient was of Italian parentage. One of the patient's parents must show sickle cells, since this trait is inherited as a Mendelian dominant. Neither parent was tested, however. The occurrence of sickle-cell anemia in white persons has been reviewed recently, with the report of 13 cases occurring in persons from Mediterranean countries, especially Italy.<sup>2</sup> This patient was Italian. The diagnosis of congenital hemolytic jaundice is ruled out in this case by the increased resistance of the red blood cells to hemolysis in solutions of hypotonic saline. There was no history of hemoglobinuria.

The characteristic symptoms of sickle-cell anemia are abdominal and joint pains in half the patients.<sup>3</sup> The predominant physical signs are jaundice and heart murmurs in over 70 per cent of the cases; in about 50 per cent, there is enlargement of the liver and heart; and in approxi-

<sup>4</sup>Associate in medicine, Harvard Medical School; associate director, Second and Fourth Medical Services (Harvard), and assistant physician, Thorndike Memorial Laboratory, Boston City Hospital.

mately one third of the cases there are pathologic changes in the lungs, ulcers or scars on the legs, fever and splenomegaly.<sup>3</sup>

Concerning the pathological physiology of sickle-cell anemia, Hahn and Gillespie,<sup>4</sup> in 1927, demonstrated that the sickled form of the red cells was produced by unsaturation of the hemoglobin by removal of oxygen from the cells. Recent observations,<sup>5,6</sup> have shown that red cells in the sickled form are strikingly more viscous than normally shaped cells. The viscosity increases as the partial pressure of oxygen is decreased, and the increased viscosity becomes manifest in vitro at about the oxygen tension of mixed venous blood. It is probable that such increases in viscosity occur in a patient with sickle-cell traits and produce a striking degree of stasis in the capillaries. This phenomenon may well account for the infarctions and abnormal destruction of red blood cells observed in certain of these patients.

These physiologic changes agree with observations that capillary blockage is the unit of pathology in sickle-cell anemia.<sup>7</sup> The pathological findings include the presence of sickle cells in dilated capillaries of the spleen, liver, kidney, lung and brain, together with thrombosis and infarction of these organs. The spleen of a child is usually enlarged, the capillaries and pulp being congested with sickled cells. Infarcts are common, and in older subjects the spleen decreases in size with fibrosis and may become extremely small. The lungs may be the site of multiple thromboses and infarcts involving many lobes. Thrombosis involving the brain may be extensive and may cause paralysis in a child as the first sign of sickle-cell anemia.

To return to the case under discussion, it is apparent that the patient had sickle-cell anemia, that the spleen, as described, showed evidence of diminished size, infarction, deposits of hemosiderin, fibrosis and congestion. The lung problem is of great importance, since it probably caused her death. At the age of three years, the child was considered to have tuberculosis, and at the ages of six, ten, twelve, eighteen and twenty the diagnosis of pneumonia was made. The best single explanation for the pulmonary lesion, especially that resulting in the atypical attack of pneumonia during the last illness, is multiple thromboses and infarcts of the lungs. The heart will probably show dilatation without valvular diseases.

DR. DONALD S. KING: We were interested in the lungs, and when I saw the patient I thought the diagnoses were Cooley's anemia and acute rheumatic fever. I believed at that time that the

joint changes were not associated with the anemia itself. We assumed that this was an atypical pneumonia, probably on a rheumatic basis. I am not at all sure that the pathologist would back that up, since this case was not quite typical of such a pneumonia. This explanation of Dr. Ham's sounds more reasonable.

#### CLINICAL DIAGNOSES

Acute rheumatic fever.  
Rheumatic pneumonia.  
Cooley's anemia.  
Sickle-cell anemia?  
Bronchopneumonia.

#### DR. HAM'S DIAGNOSES

Sickle-cell anemia.  
Fibrosis of spleen, with infarction, deposits of hemosiderin and congestion.  
Multiple thromboses and infarcts of lungs.  
Dilatation of heart.

#### ANATOMICAL DIAGNOSES

Sickle-cell anemia.  
Septicemia (hemolytic streptococcus).  
Rheumatic myocarditis, probable.  
Pericarditis, acute fibrinous.  
Acute and chronic pulmonary congestion.  
Pulmonary infarcts, multiple.  
Hyperplasia of the bone marrow.  
Operative scars: sternal biopsy; splenectomy; cholecystectomy.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: There is a certain immoral aspect to the diagnosis of this disease, I think, because it is a common observation that if one looks at a fresh sample of blood one may not see sickling, but after delay it may become quite obvious, so that the intern who is slowest perhaps stands the best chance of making the diagnosis. This patient was in this hospital on numerous occasions, at the Children's Hospital several times and at the Huntington Memorial Hospital several times, and only twice in twenty years did anyone notice sickling. Once it was questioned at the Huntington Memorial Hospital, and at the last admission here it was definitely noticed by Dr. Louis Johnson. Several scores of people examined the blood and failed to note sickling. We had a chance to make the diagnosis when splenectomy was done but did not know enough to do it. We recognized at once that this spleen was unlike anything we had seen previously. The pulp looked like the spleen of hemolytic anemia, but there were degenerative changes

in the parenchyma, including foci of fibrosis that one would not expect to see in ordinary hemolytic anemia. The clinicians for the most part thought that the patient must have Cooley's anemia, and at nearly all admissions to this hospital that diagnosis was made. On what basis the diagnosis of lymphatic leukemia was advanced, I do not know. I think it is possible that she may at some time or other have had showers of nucleated red cells, and it is my experience that nucleated red cells are frequently counted as lymphocytes by the average medical intern. I do not know that that was so, but I should strongly suspect it. We eventually sent this spleen to the Johns Hopkins Hospital, where it was looked at by Dr. Arnold R. Rich, who at one glance recognized the lesion as one due to sickle-cell anemia and said it could be nothing else.

The other findings at autopsy are of some interest. The heart was a little dilated but probably not hypertrophic, weighing 300 gm., which is, I think, within normal limits for her age and size. There were no valvular lesions. On microscopic examination, a few small foci of round cells were found in the myocardium. I have backed and filled about these many times, but a few of them are certainly indistinguishable from Aschoff bodies. It seems to me that I must therefore make a diagnosis of active rheumatic fever. There was a fibrinous pericarditis, which may have been rheumatic in origin or may have been due to a terminal hemolytic streptococcus septicemia. The lungs presented a very unusual appearance. They were heavy and extremely red. When they were cut, almost no fluid exuded from them. There were also numerous obvious infarcts. The appearance was very much like that of the most extreme form of chronic passive congestion, the so-called "cyanotic induration of the lung" that one sees with severe mitral stenosis, yet this patient had a normal mitral valve. The infarcts were numerous, and were scattered all over the lung. Most of them tended to be fairly small, 1 to 2 cm. in diameter. The vessels within the infarcts showed thromboses. Elsewhere in the lung, it was very hard to find any thrombi.

An unusual feature about the autopsy was that the blood in all the vessels and in the major chambers of the heart itself was firmly clotted, making it very difficult to decide whether there might or might not have been ante-mortem clots, or whether coagulation had occurred immediately

after death, so that ante-mortem clots might easily have been obscured in this extensive post-mortem clotting process.

The picture in the lungs is a little reminiscent of rheumatic pneumonia but not very characteristic, and I think, in view of what Dr. Ham has pointed out to us, that it is much more reasonable to assume it to have been part of the sickle-cell anemia.

The bone marrow was hyperplastic, but to my eye showed no specific changes.

A PHYSICIAN: Would not x-ray treatment have modified the spleen somewhat?

DR. MALLORY: That was what we thought when we originally saw it—that the giant cells could be explained by the fact that radiation had been given. On the other hand, we do not in practice actually see these changes in patients whose spleens have been irradiated. We should have recognized the difference if we had known more about it. To anyone familiar with this disease who happened to think of the possibility, the diagnosis should have been obvious at any time but none of us even thought of it.

Have you any further comment, Dr. Ham?

DR. HAM: The wet-smear method of detecting sickle cells is usually satisfactory, but an immediate result may be obtained by the removal of oxygen from the red cells by equilibration of the blood with carbon dioxide or nitrogen. In this procedure, from 3 to 5 cc. of whole blood is introduced into a 250-cc. tonometer or Erlenmeyer flask equipped with a two-hole stopper. The blood is equilibrated with the gas for ten to fifteen minutes; a small amount of blood is then removed with a pipette, and a drop is placed immediately on a slide under a cover slip. This preparation is then examined for sickle cells. The blood cannot be dried in room air, since the cells are re-oxygenated and revert to the nonsickled form.

## PHYSICIANS AND CIVILIAN DEFENSE

THE recent appearance of a handbook, *Organization Medical Division and Care of Injured Civilians*, issued by the Medical Division of the Massachusetts Committee on Public Safety, emphasizes preparation for civilian defense in America. Whether the plans so well laid will ever have to be called into being, no one can say, but all should be grateful that the Governor has seen fit to establish a mechanism for the protection of civilians. In America, so distant from the shores of Europe, it appears that danger is minimal, but many countries that have thus sought a way out of the effort of preparedness have been guilty of gross misjudgment and have suffered ugly and terrible consequences.

The Public Safety Committee of Massachusetts is composed of five divisions. Two of these, devoted to planning and publicity, are largely auxiliary and do not extend to any degree into the local communities. The Protection Division largely concerns itself with the work of the air-raid wardens and their many different tasks; 10,000 ARP Service men have already been through the schools, and 16,000 are now in training. The Public Services and Supplies Division has spread its network of regional directors and contact men throughout the State; their task deals with the maintenance of power, heat, light, communications, adequate food supplies and so forth. The Health and Social Services Division has three duties. The Public-Health Section looks after the health of people in preparation for war, the sanitary health measures during an emergency and the health measures that may be necessary after an emergency. The Social Services Section is concerned with activities promoting better morale, the social conditions in the environments of large army camps, the care of families rendered destitute by a grave emergency and the rehabilitation of individuals and populations after an emergency has passed. The Medical Division\* looks after the civilian from the time of injury until his restoration to active life.

The handbook was written to standardize and simplify the medical care of civilian casualties, whether from fire, bombs, bullets or shells, and with certain modifications, the British scheme has been followed. The authority for action when an "incident" occurs rests ultimately in the hands of the chief medical officer of the community. He sends to the scene a squad from the ARP Service. These men, already trained in first aid, enter the demolished houses and remove the injured. The walking wounded are guided, and those severely injured are carried on stretchers to a mobile medical first-aid post, which the chief medical officer has already established at the scene of disaster. Traction splints and bandages are applied, when necessary, and those persons who

\*Because of the experience in the recent war games, it has seemed wise to separate the Medical Section from the Public Health and Social Services sections, and the Medical Division is now a separate unit.

need hospitalization are immediately transferred by ambulance to the nearest hospital. The patients in hospitals in metropolitan areas are transferred the next day to large base hospitals in the rural districts, such as the Tewksbury State Hospital and various tuberculosis sanatoriums.

The chief medical officer and the local medical committee in each community have the responsibility of setting up these plans. In the large metropolitan areas, it has been suggested that the task be broken down so that one physician organizes the medical first-aid posts, another, ambulance transportation, and another, the hospitals. To assist the chief medical officers, regional directors have been appointed whose areas of jurisdiction largely correspond with those of the district medical societies.

The scheme for this vitally necessary undertaking is reasonable and workable, and is as good as if not better than that devised in any other state. All Massachusetts physicians should gladly and willingly complete the task that has been placed before them.

---

## THE COMMONWEALTH FUND

THE Commonwealth Fund was established in 1918 by Mrs. Stephen V. Harkness to "do something for the welfare of mankind." According to its twenty-second annual report, grants amounting to more than \$2,000,000 were given for philanthropic purposes during the past year. A third of this total was devoted to medical research and medical education, and nearly half was contributed to various health services throughout the country, chiefly to rural health departments, and rural hospitals. Grants made in 1940 and in former years for medical research and education amounted to \$545,060, a large part being given to thirty-six medical-research projects at sixteen institutions. As an aid to medical education, the fund awarded fellowships for advanced study to seventeen teachers in medical schools. Special assistance was given to the teaching of preventive medicine at the Long Island College of Medicine, New York University College of Medicine, Tufts College Medical School, Tulane University of Louisiana School

of Medicine and Vanderbilt University School of Medicine, and to the Department of Psychiatry at the University of Louisville. Other significant contributions went to local public-health services and rural hospitals.

Of particular interest in the current report, however, is the grant of \$135,000 to meet special war needs abroad. Gifts were made to the American Red Cross and the British War Relief Society. The Child Guidance Council supported by the fund has proved its usefulness by its work among the children evacuated from London and other cities.

The Commonwealth Fund has indeed adhered to its motto: "To do something for the welfare of mankind." Its indispensable support of numerous efforts to solve the problems of human welfare and happiness and its contribution to the relief of suffering in war-torn Europe echo the motive of the fund's foundation in 1918. Its achievements remain not only a tribute to the selflessness of its founder and the zeal of its directors but also an inspiration to private philanthropy.

---

## OBITUARY

### GERALD BLAKE

1880-1941

The tradition of medicine was strong and deep in "Jerry" Blake. His father and his brother were doctors. His father was the much beloved Dr. John G. Blake, for many years on the staff of the Boston City Hospital, a fine general practitioner of the old school, who, when he moved to Boston's Back Bay, liked to recall the older days of Boston's South End. His mother was well known to the readers of the *Boston Transcript* under the initials of "M. E. B."

He grew up in a large family, mostly boys. All were gay, with a family talent for singing songs of infectious mirth and of interminable verses. One readily recalls the "Whizz Fish" and the "Bummers Hotel."

In Harvard College, at a time when the Harvard Band was more a manifestation of nearly spontaneous undergraduate enthusiasm than today's expression of nearly musical talent, "Jerry" occasionally beat the bass drum because the band had to have a bass drummer.

In the Harvard Medical School, "Jerry" was the best liked man in the Class of 1905—friendly,

hard working, intelligent, modest but effectively loyal led him to choose an internship at the Boston City Hospital. He then entered service in Boston. Of course, with his ability, integrity and his personality, he was eminently successful professionally. He greatly admired medical research, but his busy, full life of practice left him no time, and indeed his modesty and honesty made him feel that he was not fitted for research. In any event, his patients and his family came first.

He went through the various stages on the teaching staff of the Massachusetts General Hospital, and for a number of years held the position of visiting physician. The ward patients loved him for his sympathy, his humor and his excellent bedside manner. The interns and residents learned much from him that they had not found in books or lectures. On ward rounds one morning, an over-tired intern delivered a long dissertation on some topic not particularly related to the patient beside whose bed they had stopped. The patient became very apprehensive over the earnestness of the young man and over the medical jargon. He patted the patient and looked kindly at the intern. Finally, he quietly said to the intern, who had paused to get his breath: "What kind of razor do you use? You get a useful close shave."

Over a dozen years ago, Jerry had a severe illness. After this, he had albuminuria and a microscopic hematuria, both of which persisted. His blood pressure slowly began to climb. He had attacks of pulmonary apoplexy, several episodes of minor cerebral accidents and a coronary embolism. After the attack of coronary thrombosis he developed angina, which plagued him daily in his last years of his life. He never complained; he insisted on continuing his large active practice, which he did with undiminished excellence. He grew thin because eating gave him angina. He still had the picture of him, tall and thin, slowly wasting—by this time he had acquired a Parkinsonian syndrome—up the Phillips House steps. "How are you, Jerry?" His face would light up with his old delightful smile, and the answer would be, "Oh, fine." And this kept up for months and months, until his complete incapacity made him consent to take his vacation ten days ahead of the time he had stipulated for himself, despite pleas and protests. On his way to his holiday, he developed his final coronary thrombosis. A great practitioner and a lovable personality had become a hero for years. "Jerry" had had what it takes to make a hero.

## MEDICAL EPONYM

### KOPLIK'S SPOTS

This sign was described by Henry Koplik (1858-1927) in the *Archives of Pediatrics* (13: 918-922, 1896), in an article entitled, *The Diagnosis of the Invasion of Measles from a Study of the Exanthema as It Appears on the Buccal Mucous Membrane*.

One of the most, if not the most, reliable sign of the invasion of measles has fully failed to receive due attention. If we look in the mouth at this period [during the first twenty-four to forty-eight hours of the invasion], we see a redness of the fauces, perhaps a few spots on the soft palate. On the buccal mucous membrane and the inside of the lips, we invariably see a distinct eruption. It consists of small irregular spots, of a bright red color. In the center of each spot, there is noted, in strong daylight a minute bluish white speck. These red spots, with accompanying specks of a bluish white color, are absolutely pathognomonic of beginning measles, and when seen can be relied upon as the forerunner of the skin eruption. As the skin eruption begins to appear and spreads, the eruption on the mucous membrane becomes diffuse. The buccal eruption begins to fade even while the skin exanthema is at its height. In cases where this eruption has been absent, I have always found that my exclusion of a probable attack of measles was correct.

### SECTION OF OBSTETRICS AND GYNECOLOGY\*

#### PREMATURE SEPARATION OF THE PLACENTA, FOLLOWED BY FATAL SHOCK AND HEMORRHAGE

A thirty year-old para VIII who had been followed adequately during pregnancy began to flow very freely at term, and was consequently sent into the hospital.

The previous seven pregnancies had terminated in normal deliveries.

On entry the patient had a tender uterus and was flowing freely. No mention was made whether the fetal heart was audible. Vaginal examination at this time showed that the cervix was dilated sufficiently to admit two fingers, and no placenta was felt, no treatment was given. Two hours later, a cesarean section was performed, after a diagnosis of premature separation of the placenta had been made. The placenta was found lying free in the uterine cavity, and a stillborn fetus

\*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters should be addressed to Dr. Raymond S. Titus, Secretary, 330 Dartmouth Street, Boston.

was delivered. The patient's condition was apparently very poor at the end of the operation. She was given intravenous glucose but was not transfused. Four hours after the operation, she died, apparently from shock and hemorrhage.

*Comment.* This case illustrates quite well how cases of premature separation of the placenta should not be treated. It is a little unusual in prematurely separated placentas to have excessive external hemorrhage; more frequently, external hemorrhage is slight, and internal hemorrhage is great. It would have been very much better to have treated this patient conservatively. She was a multipara, and although not in labor, she certainly had a cervix that was approximately at term, since it is reported that the cervix was dilated to admit two fingers. The conservative treatment would have consisted in tight cervical and vaginal packing, a Spanish windlass, transfusion and small doses of pituitary extract. Frequently, cases of separated placenta are associated with increased blood pressure and albuminuria, but these were not present in this patient. In primiparas when the fetus is still alive cesarean section may be the operation of choice. In these cases, only 1-minim doses of pituitary extract should be used at intervals of approximately an hour until labor is established. The mortality from this complication when so treated has dropped very appreciably, but conservative treatment cannot guarantee against fatality. If the patient is exsanguinated before the treatment is instituted or if she is extremely toxic, with complete suppression of the urine, nothing can prevent a fatal outcome. The shock of an abdominal operation on a patient such as this is often too much for Nature to combat.

## MISCELLANY

### BOSTON UNIVERSITY SCHOOL OF MEDICINE OFFERS HOSPITALIZATION SERVICE

Hospitalization service will be offered to students of Boston University School of Medicine throughout the present academic year for a five-dollar fee or a donation to the blood bank, President Daniel L. Marsh and Dean Bennett F. Avery of the school recently announced. Under the hospitalization plan, the medical students will receive complete medical care during the school year. The program has been developed under a new agreement, now going into effect with the Massachusetts Memorial Hospitals, to aid medical students needing hospital care throughout the academic year.

## NOTE

Dr. C. Sidney Burwell, dean of the Harvard Medical School, recently announced that Dr. Derek E. Denny-Brown, of London, had arrived in Boston from England

to take up his duties as professor of neurology and director of the Neurological Unit, Boston City Hospital. Dr. Denny-Brown's appointment dates from September, 1939, but during the interval he has been on leave of absence serving as a major in the British Medical Corps. Since January, 1940, he has been the officer in charge of the Medical Division, Military Hospital for Head Injuries, in England. In his combined duties here he will take active part both in the teaching of medical students and in the care of the sick in the City of Boston.

## CORRESPONDENCE

### PREMARITAL HEALTH EXAMINATIONS

*To the Editor:* The Department of Public Health has sent to all Massachusetts physicians a letter describing their responsibilities under the new premarital health-examination law. It is requested that the *Journal* print a list of the laboratories at present approved by the department for performing serologic tests for syphilis, and certain sections of the general marriage laws with which physicians should be familiar.

The blood specimen for serologic examination for syphilis should be sent to the Wassermann Laboratory, 25 Shattuck Street, Boston, or to a laboratory approved by the department. The following laboratories have so far been approved:

- Boston
  - Beth Israel Hospital
  - Boston Health Department
  - Leary Laboratory
  - Massachusetts General Hospital
  - Peter Bent Brigham Hospital
- Brockton
  - Health Department
- Fall River
  - Truesdale Hospital
- Fitchburg
  - Burbank Hospital
- Holyoke
  - Providence Hospital
- Montague
  - Farren Memorial Hospital
- New Bedford
  - St. Luke's Hospital
- Pittsfield
  - St. Luke's Hospital
- Springfield
  - Mercy Hospital
- Tewksbury
  - State Infirmary
- Worcester
  - City Hospital
  - St. Vincent Hospital

Presumably the city laboratories will do blood tests only for local physicians, and the hospital laboratories only those of patients in the hospitals or outpatient departments.

The following sections taken from the Marriage Laws answer most of the questions which marriage applicants will ask physicians:

## General Laws, Chapter 207 (as amended)

Section 11 No marriage shall be contracted in this commonwealth by a party residing and intending to continue to reside in another jurisdiction if such marriage would be void if contracted in such other jurisdiction, and every marriage contracted in this commonwealth in violation hereof shall be null and void

Section 12 Before issuing a license to marry a person who resides and intends to continue to reside in another state, the officer having authority to issue the license shall satisfy himself, by requiring affidavits or otherwise, that such person is not prohibited from intermarrying by the laws of the jurisdiction where he or she resides

Section 19 Persons intending to be joined in marriage in the commonwealth shall, not less than five days before their marriage, cause notice of their intention to be filed in the office of the clerk or registrar of the town where each of them dwells, or, if they do not dwell within the commonwealth, in the office of the clerk or registrar of the town where they propose to have the marriage solemnized. In computing the five-day period specified in this section and in determining the fifth day referred to in section twenty eight, Sundays and holidays shall be counted

Section 20 (as amended by Chapter 127, Acts of 1933) The clerk or registrar shall require written notice of intention of marriage, on blanks furnished by the state secretary, containing such information as is required by law and also a statement of absence of any legal impediment to the marriage, to be given such clerk or registrar under oath, by both of the parties to such intended marriage if both dwell in his town, or, if the parties dwell in the different towns within the state, or if one dwells outside the state, by the party dwelling in his town, or, if both dwell outside the state, by both such parties, provided that if a registered physician makes affidavit to the satisfaction of the clerk or registrar that a party so required is unable, by reason of illness, to appear, such notice may be given on behalf of such party, by his or her parent or legal guardian, or, in case there is no parent or legal guardian competent to act, by the physician certifying to the illness, or by the other party irrespective of such other party's residence. The oath to such notice shall be to the truth of all the statements contained therein whereof the party subscribing the same could have knowledge, and may be given before the clerk or registrar or before a regularly employed clerk in his office designated by him in writing and made a matter of record in the office. No fee shall be charged for administering such oath. In towns having an assistant clerk or registrar, he may administer the oath.

PAUL J. JANNAUH, M.D.  
Commissioner of Public Health

State House  
Boston

## NOTICES

## BOSTON LYING IN HOSPITAL

There will be a meeting of the Journal Club of the Boston Lying in Hospital on Thursday, October 30 at

8 p.m. Dr. Norris W. Vaux, professor of obstetrics at Jefferson Medical College of Philadelphia, will speak on 'Some Local Uses of Estrogenic Hormones in Obstetrics and Gynecology'

NEISSERIAN MEDICAL SOCIETY  
OF MASSACHUSETTS

The annual meeting of the Neisserian Medical Society of Massachusetts will be held on Wednesday, October 29, at 7 p.m., at the Hotel Kenmore, Boston

## PROGRAM

Dinner

Election of officers

Speaker Ernest B. Howard, M.D., director, Division of Genitoinfectious Diseases, Massachusetts Department of Public Health

Round Table Discussion Gonorrhea and National Defense "

## CARNEY HOSPITAL

The monthly clinical meeting and luncheon of the staff of the Carney Hospital will be held in the auditorium of the Carney Hospital on Monday, October 20, at 11 30 a.m.

## PROGRAM

Case Reports

Clinicopathological Conference.

Discussion by Drs. William Flynn, Joseph O'Brien, Norman A. Welch and Roger C. Graves

Physicians and medical students are invited to attend

## JEWISH MEMORIAL HOSPITAL

A diagnostic therapeutic conference will be held at the Jewish Memorial Hospital on Thursday, October 23, at 11 a.m. Dr. Elliott P. Joslin will speak on 'Diabetic Problems'

Interested physicians and medical students are cordially invited to attend

## EDWARD K. DUNHAM LECTURES

The Faculty of Medicine of Harvard University has announced that the following lectures, prepared by Dr. Rudolf Schoenheimer, formerly associate professor of biological chemistry, Columbia University College of Physicians and Surgeons, will be delivered by Professor Hans T. Clarke, under the Edward K. Dunham Lecture ship for the Promotion of the Medical Sciences

Tuesday, October 28 The Chemical Reactions of the Body Fats

Wednesday, October 29 The Chemical Reactions of the Body Proteins

Thursday, October 30 The Dynamic State of the Body Constituents

These lectures are scheduled for 5 p.m. at the Harvard Medical School Amphitheater, Building C

## NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

The regular monthly meeting of the New England Society of Physical Medicine will be held on Wednesday evening, October 22, at the Hotel Kenmore, Boston.

The council will meet at 6:00, and an informal dinner will be held in the Empire Room at 6:30. At 8:00, Dr. Augustus Thorndike, Jr., will speak on "The Effects of Physical Therapy on Athletic Injuries."

All members of the medical profession are cordially invited to attend.

## CUTTER LECTURE

Sir William Wilson Jameson, chief medical officer, Ministry of Health, London, will give the Cutter Lecture on Preventive Medicine at the Harvard Medical School on Wednesday, October 22. His subject will be "Public Health in Britain at War," and the lecture will begin at five o'clock in the amphitheater of Building E. These lectures have been given annually since 1912. The medical profession, medical and public-health students and others interested are invited to attend.

## BOSTON DOCTORS' SYMPHONY ORCHESTRA

The Boston Doctors' Symphony Orchestra will rehearse, under Alexander Thiede, every Thursday at 8:30 p.m. at Station WMEX, 70 Brookline Avenue, Boston. Those interested in becoming members should commu-

nicate with Dr. Julius Loman, 520 Beacon Street, Boston (KEN 3200 or LON 2155).

## THOMAS WILLIAM SALMON MEMORIAL LECTURES

The Salmon Committee on Psychiatry and Mental Hygiene invites the members of the medical profession and their friends to the ninth series of Thomas William Salmon Memorial Lectures.

This series will be given by Dr. Robert D. Gillespie, psychiatric specialist of the British Royal Air Force. The lectures will be given on November 17 and 18 in New York City, November 19 in Toronto, November 21 in Chicago, November 22 in New Orleans, November 27 in San Francisco and November 30 in Philadelphia. Dr. Gillespie will speak on "Psychoneuroses in Peace and War, and the Future of Human Relationships."

## MASSACHUSETTS PUBLIC HEALTH ASSOCIATION

A meeting of the Massachusetts Public Health Association will be held at the Commander Hotel, Cambridge, on Thursday, October 30.

The section meetings will be held at 3 p.m. A buffet supper (\$1.25 per cover) will be served at 6 p.m. Following the general business meeting at 7 p.m., seven experts will conduct a symposium, "New Developments in Prophylactic Immunizations."

## RECEPTION FOR DR. HYMAN MORRISON

A reception and tea in honor of Dr. Hyman Morrison will be given October 19, at 2:30 p.m., at the Beth Israel

Hospital, celebrating his sixtieth birthday. A sum of money has been collected for the purpose of establishing the Hyman Morrison Laboratory for Research in Medicine at the National University, Jerusalem. A check for this purpose will be presented to Dr. Morrison on this occasion.

## SOCIETY MEETINGS AND CONFERENCES

### CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, OCTOBER 19

#### MONDAY, OCTOBER 20

- \*11:30 a.m. Monthly clinical meeting and luncheon of the staff, Carney Hospital auditorium.
- 12:15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital amphitheater.

#### TUESDAY, OCTOBER 21

- \*9:00-10:00 a.m. Medical clinic. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.
- \*12:00 m. The Physician in National Defense. Dr. Donald E. Currier. South End Medical Club, headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston.
- 12:15-1:15 p.m. Clinicoroentgenological conference. Peter Bent Brigham Hospital amphitheater.

#### WEDNESDAY, OCTOBER 22

- \*9:00-10:00 a.m. Acne, Hirsutism and Menstrual Disorders. Dr. C. H. Lawrence. Joseph H. Pratt Diagnostic Hospital.
- 10:00 a.m. John T. Bottomley Society. Carney Hospital.
- \*12:00 m. Clinicopathological conference. Children's Hospital.
- \*5:00 p.m. Public Health in Britain at War. Sir William Wilson Jameson. The Cutter Lecture. Harvard Medical School, amphitheater of Building E.
- \*8:00 p.m. The Effects of Physical Therapy on Athletic Injuries. Dr. Augustus Thorndike, Jr. New England Society of Physical Medicine, Hotel Kenmore, Boston.

#### THURSDAY, OCTOBER 23

- \*8:30 a.m. Combined clinic of the medical, surgical, orthopedic and pediatric services of the Children's Hospital and the Peter Bent Brigham Hospital, at the Peter Bent Brigham Hospital.
- \*9:00-10:00 a.m. Medical clinic. Dr. S. J. Thannhauser. Joseph H. Pratt Diagnostic Hospital.
- \*11:00 a.m. Diabetic Problems. Dr. Elliott P. Joslin. Jewish Memorial Hospital.

#### FRIDAY, OCTOBER 24

- \*9:00-10:00 a.m. Physical Fitness in Late Maturity. Dr. Robert T. Monroe. Joseph H. Pratt Diagnostic Hospital.

#### SATURDAY, OCTOBER 25

- \*9:00-10:00 a.m. Presentation, with discussion, dispensary and district cases. Joseph H. Pratt Diagnostic Hospital.
- \*Open to the medical profession.

## THE ROLE OF THE ROENTGENOLOGIC EXAMINATION IN THE DIAGNOSIS OF INTESTINAL OBSTRUCTION\*

EUGENE P. PENDERGRASS, M.D.†

PHILADELPHIA

IN studying patients who have symptoms suggestive of intestinal obstruction, some of the problems that the clinician must answer if possible include the following: Is an obstruction present? Does it involve the stomach, the duodenum, the small intestine, the colon or a combination of these organs? Is the obstruction single or multiple? Is the obstruction complete or incomplete? What is the cause of the obstruction? Is it an acute occlusion, or is it the final closure of a slowly developing lesion?

The most valuable aid on which the clinician may rely is probably the correct interpretation of observations gleaned from a carefully planned roentgenologic examination of the abdomen or the gastrointestinal tract. The discussion of such observations is limited, for the most part, to those concerning the small intestine and colon.

### PRESENCE OF OBSTRUCTION

Patients with obstructive lesions in the intestinal tract, some of which are almost complete, do not always present classic symptoms. Occasionally, this is true of a lesion involving the pylorus and duodenum. In such cases, the diagnosis can be made only after the patient has had a roentgenologic study of the gastrointestinal tract.

As a rule, the patient with symptoms of an acute abdominal condition is referred to the radiologist for a survey examination of the abdomen. If the condition is such that he can be moved with safety, examination of the abdomen includes a fluoroscopic study in the horizontal and semierect positions. The advantage of such a procedure is to determine the extent of the movement of the domes of the

diaphragm and to make, if necessary, roentgenograms of important fluoroscopic observations.

The minimum requisite of such a study is a roentgenogram of the abdomen in the anteroposterior position. Additional roentgenograms that may reveal valuable information are as follows: posteroanterior and lateral films with the patient in the recumbent position; anteroposterior or posteroanterior films with the patient lying on the left or right side; and anteroposterior or posteroanterior films with the patient in the erect position. Whenever possible, the shadows of the domes of the diaphragm should be seen on the roentgenogram, and a lateral view of the pelvic region should be available for study of gas shadows in the rectum.

The purpose of the survey is to determine the presence and location of any demonstrable gas in the intestinal tract or abdomen, the presence or absence of muscle shadows and the preperitoneal fat lines, and to locate if possible any abnormal soft-tissue lesions.

Gas is present throughout the alimentary canal, but under normal conditions (except in infants and very small children) one does not see gas shadows in the roentgenograms of the small intestine. In the stomach and colon, gas shadows are found frequently in roentgenograms of the abdomen. Wangenstein<sup>1</sup> explains the inability to see the gas shadows in the small intestine as being due to the intimacy of the admixture between the fluid and gas. Under conditions of stasis, however, the gas separates from the fluid and can be demonstrated readily.

According to Wangenstein, gas in the obstructed intestine consists of the gas produced by digestive processes, that diffusing from the blood into the intestinal lumen, and swallowed atmospheric air. Under experimental conditions, swallowed air accounts for 68 per cent of the gas shadows found

1Director, Department of Radiology, Hospital of the University of Pennsylvania.

in intestinal obstruction, the remainder of the shadows being due to the other two sources. Wangensteen says that one can demonstrate abnormal gas shadows on the roentgenograms of experimental obstructive lesions after four or five hours. It is not known how long it takes for gas shadows to become apparent in intestinal obstruction in human beings, but it is common knowledge that chemical irritants such as Diodrast cause visible gas shadows in the small intestine in a few minutes.

Abnormal gas shadows in the small intestine and colon may occur as a result of a variety of conditions, most of which the radiologist must bear in mind to make a careful correlation of the roentgenologic and clinical observations before he attempts to arrive at a provisional diagnosis. Some of the things, other than intestinal obstruction, that produce abnormal gas shadows and modify the roentgenologic signs are as follows: morphine and many other sedative drugs; peritoneal irritation from any cause, such as retroperitoneal hemorrhage due to an injury; dysentery and many bacterial and chemical irritants, and nutritional deficiencies; a ruptured graafian follicle; and general conditions, such as diabetes and sickle-cell anemia.

If the radiologist and the clinician, after study of the data, conclude that the abnormal gas shadows are due to an obstruction, the next problem to decide is where it is.

#### LOCATION OF OBSTRUCTION

With the exception of obstruction due to hypoproteinemia, it is not the purpose of this presentation to discuss obstructive lesions involving the stomach and duodenum.

The radiologist is frequently called on to examine patients who have had reconstructive operations performed on the stomach. Some of these patients continue to vomit, and after a barium meal, the stomach may not empty for many hours, and the radiologist and surgeon often conclude that the patient has a mechanical obstruction due to adhesions or some defect resulting from the operation.

My experience and that of Barden et al.<sup>2</sup> indicate that the stomach frequently empties very slowly for approximately three weeks after operation, owing to the influence of operative trauma, hypoproteinemia and possible vitamin deficiencies. After the return of such factors to normal, the stomach empties without the slightest difficulty. If such factors account for the patient's symptoms and are recognized, an unnecessary operation may be prevented.

In the study of roentgenograms of the abdomen,

experience has shown that if the gas shadows are limited to the colon, and the symptoms are acute, the obstruction is likely to be found in that organ. Wangensteen,<sup>1</sup> Rigler and Lipschultz<sup>3</sup> and many others have called attention to this observation in the past. Wangensteen states that the ileocecal sphincter and valve operate in the manner of a check valve, allowing gas and fluid from the small intestine to be swept into the colon, but that regurgitation is prevented by the sphincter. In my experience, the small bowel rarely participates in a colonic obstruction unless the process is chronic or extends beyond the confines of the colon, or unless the lesion is associated with a spreading infection.

A survey examination of the abdomen may afford all the information necessary to diagnose and locate the position of a colonic obstruction. If it does not, a barium enema may be indicated to meet the requirements of the surgeon who wishes to know the nature of the pathologic process and the degree and position of the obstruction. Occasionally, it is impossible to administer a barium enema because of the patient's inability to retain it. At other times, the illness of the patient and the severe distention of the colon make one hesitate to subject the patient to the manipulation that such an examination necessitates, owing to the danger of perforation of an already overdistended and necrotic bowel.

If the abnormal gas shadows are limited to the colon, the obstruction is likely to be mechanical. I have seen only one patient who suffered from a paralytic distention of the colon produced by a spinal-cord lesion that simulated and had to be differentiated from an organic obstruction. As a rule, a paralytic ileus causes distention of the small and large intestine and offers no difficulty in the differential diagnosis.

Rigler and Lipschultz<sup>3</sup> describe the roentgenologic signs that they consider helpful in making a diagnosis of volvulus of the sigmoid. These signs include the increased size of the sigmoid, most of the lumen of which is found high up in the abdomen outside the pelvis and to the right of the midline, the presence of unusual amounts of fluid and the demonstration of a double point of obstruction. A barium enema may be necessary to assist in determining the diagnosis. In a patient with volvulus whom I studied, the administration of the enema was greatly facilitated by having the patient get in the knee-chest posture. A similar position is recommended in all patients who have large pelvic masses.

If the patient has a primary lesion of the colon, such as diverticulitis or an infected carcinoma, the

small intestine, in addition to the colon, is frequently distended. The use of the stethoscope assists in diagnosing or excluding a paralytic ileus, and a barium enema frequently helps to determine the nature of the pathologic process. This is especially significant when the gas shadows of the small intestine simulate the haustral markings in the colon.

A colonic lesion is apter to result in perforation than a lesion of the small intestine is, and the cecum is more vulnerable to distention than other portions of the colon. Roentgenograms are made in the erect and the lateral decubitus positions to demonstrate free gas in the peritoneal cavity. Thick shadows of the intestinal walls may be due to peritonitis. The loss of the shadow of the preperitoneal fat line or the absence of the lumbar-muscle shadows should be evaluated, because such observations may indicate peritonitis.

The clinical signs of obstruction of the small intestine are much more definite than those of colonic obstruction. The observation of varying amounts of distention of the small intestine is the only roentgenologic evidence of such a condition. Until a few years ago, the radiologist without the aid of the opaque meal was unable to demonstrate the site and nature of the obstructive lesion. Now, through the agency of a multiple-lumened tube,<sup>4</sup> it is possible not only to intubate the small intestine but also to determine the position and nature of the obstructive lesion and the completeness of the obstruction.

The procedure of intestinal intubation in obstruction consists in the passage of the tube down the intestine until it stops, or, if the obstruction is paralytic, until the obstruction has been overcome. In mechanical obstruction, it is possible to inject a thin suspension of barium and determine whether one is dealing with an intrinsic lesion, such as a tumor, or an extrinsic lesion, such as adhesions. If, after the barium has been injected, the opaque suspension regurgitates proximally along the barrel of the tube, one suspects an obstructive lesion. Colonic lesions are likely to cause the tube to stop progressing in the small intestine in the right iliac fossa owing to spasm of the ileum. Experience leads me to suggest that whenever the tube stops in the ileum one should administer a barium enema to diagnose or exclude a colonic lesion before making a diagnosis of an organic ileal obstruction.

One of the most frequent errors in interpretation has to do with the false impression of progression of the barium that is injected into the intestine by way of the Miller-Abbott tube. The sequence of observations may be as follows: the double-lumened tube stops in the right lower quadrant;

the tip of the tube, in progressing to that point, has allowed the small intestine to telescope over the barrel of the tube; the balloon is deflated and 20 cc. of thin barium suspension is injected into the intestine; following the deflation of the balloon, the portion of the small intestine that has telescoped over the tube begins to readjust itself, thus allowing barium to escape beyond the tip of the tube even in the presence of a complete obstruction. Obviously, the barium does not progress beyond the point of complete obstruction, but the apparent progression of barium is due to the unraveling of the bowel from the tube. Evidence of pleating of the tube proximal to the balloon should always be looked for, and the patient should continue to swallow the tube until pleating has disappeared before one may be sure that the tip will not retreat up the intestine on deflation of the balloon.

The procedure of intubation has many other important functions to fulfill. Some of the purposes that have been recorded by Abbott<sup>5</sup> include the following: to determine the nature of the obstruction; to determine fluid and salt loss; to relieve colic and vomiting by decompression of the distended bowel; to return peristalsis by relief of overdistention; to render operations elective rather than emergency procedures; to facilitate surgical procedures (especially in multiple obstruction); and to decrease the likelihood of postoperative leaks.

Many objections have been raised to the procedure of intubation. The first is the time required to pass the tube. A physician experienced in intubation is essential. In recent months, Abbott<sup>6</sup> has been able to pass the tube into the duodenum much more rapidly by the assistance of the rigidity produced by a piano wire placed in the double-lumened tube. Secondly, it is not always possible to aspirate the contents from the intestine. Thirdly, the tube is sometimes found to be obstructed after it has been passed. The employment of a nurse to keep the tubes clean should obviate any such complaint. Fourthly, in colonic lesions, spasm of ileum may cause faulty obstruction of the tube. Fifthly, the procedure may fail to decompress the colon, or the small bowel in cases with multiple obstructions. Finally, there is the delay in operation due to the loss of time while intubation is being attempted.

There are many suggestions that have been and might be made to help one overcome the objections just detailed, but most of these drawbacks are easily obviated if an experienced team is developed in each hospital. When that time comes, the high mortality of intestinal obstruction will become a relic of the past.

## EXTENT OF OBSTRUCTION

Most of the incomplete obstructions are studied by either the barium meal or enema, or both; they are often unsuspected. Intestinal obstruction after operation is often incomplete, and frequently occurs as a result of inflammatory adhesions or of adhesions in addition to inflammation or chemical imbalance in the tissues. If such a patient has a partial obstruction of the small intestine the Miller-Abbott tube, if passed, will stop at the site of the obstruction. Then, if barium is injected through the tube, it will progress in a caudal direction, and the nature of the obstructing condition can often be diagnosed. Such information is extremely valuable.

If the small bowel is completely obstructed, nothing will pass through it, and if barium is injected through a Miller-Abbott tube, it will regurgitate along the barrel of the tube. The complete obstruction may be temporary, particularly in cases that have been successfully intubated and have had the electrolyte balance re-established.

## MULTIPLE OBSTRUCTIONS

The diagnosis of multiple obstructions on the plain roentgenogram of the abdomen may be suspected but is exceedingly difficult to substantiate.

The multiple obstructions that one sees may be anything imaginable, but as a rule they fall into several categories: multiple obstructions of the small bowel that are due to adhesions or metastatic cancer (frequently ovarian); those of the small and large bowel caused by tumors (Hodgkin's disease, ovarian neoplasm and so forth); those of the small intestine and colon due to the effects of irradiation; those of the small and large bowel due to an inflammatory lesion (pelvic abscess) or granulomas, such as regional ileitis; those of the colon due to a tumor and an inflammatory process elsewhere, such as diverticulitis.

If the procedure of intubation is employed, the radiologist may frequently make a diagnosis of multiple obstruction on the basis of the following observations. The Miller-Abbott tube may fail to progress beyond a certain point, and gas-distended loops of small intestine may be present beyond the tip of the Miller-Abbott tube; the tube may fail to progress beyond the left lower quadrant, with either gas-distended loops of small intestine distal to the tip of the tube or a distended large bowel, or both; and there may be an obstruction to the barium injected through the tube (with the exception of false ileal obstruction), together with an obstruction demonstrable by a barium enema.

## CAUSE OF OBSTRUCTION

The obstruction is often the final closure of a slowly developing lesion, and such a possibility should be kept in mind. Other causes of obstruction may be many things and conditions, a number of which have already been discussed.

Intussusception may produce strangulation. It is imperative to recognize this condition because a disturbance in the blood supply may be produced without much clinical evidence. This, according to Wangenstein,<sup>1</sup> is due to the sheathing of the gangrenous portion of the bowel by the enveloping walls of the intestine.

If barium can be given by mouth, the nature of the lesion is readily recognized by the large filling defect of the tumor or intussusception, or both, by the narrow lumen of the intestine in the vicinity of the intussusception, except when the intussusception herniates through a gastroenterostomy opening, and by a barium enema, the filling defect of the advancing intussusception in the colon being readily demonstrated. If no opaque mixture is administered, the gas in the loops of intestine proximal to the point of obstruction is readily demonstrated, but when the lesion occurs in infants and children, the observation of gas shadows may be of no assistance, since these shadows are found normally in children up to several years of age. The oblong soft-tissue shadow of the intussusception is also diagnostic.

The roentgenologic observations in strangulated obstructions from other causes are quite different from those just described. One sees tremendous distention of the small intestine when the process involves that organ. In addition, some overdistention of the large bowel may be produced by the peritoneal irritation.

There are a number of conditions that may produce roentgenologic appearances similar to those of a strangulated obstruction. In my experience, some of these have included acute pancreatitis, twisted ovarian cyst, sickle-cell anemia, diabetes, subacute drug (morphine) effects, mesenteric occlusion, ruptured graafian follicle and paralytic ileus. The findings of the clinicians and surgeons must be correlated with the roentgenologic findings before one can make a diagnosis, and, even then, errors will occur.

The question of intubation is being considered more frequently even in those cases in which strangulation is thought to be present. Although the viewpoint of clinicians and surgeons is that only those cases that can be safely delayed should be intubated, I have recently heard conservative surgeons who have had large and successful experiences state that they recommend the passage of

the tube while the patient is being prepared for operation.

### SUMMARY

In a very general way, the roentgenologic signs that might assist in the diagnosis of intestinal obstruction are considered under the following headings: the presence, location, completeness, number and cause.

Some of the experiences with intubation that are of interest to the radiologist are recorded,

particularly those that may lead to errors in diagnosis.

## INDICATIONS FOR THE USE OF THE MILLER-ABBOTT TUBE\*

W. OSLER ABBOTT, M.D.†

PHILADELPHIA

IN a broad sense, the indications for the use of the Miller-Abbott technic of intestinal intubation<sup>1</sup> may be classed as experimental, diagnostic and therapeutic.

### EXPERIMENTAL PROCEDURES

The experimental employment of the method, begun nine years ago at the University of Pennsylvania after two decades of preliminary trial, is worthy of mention because the special clinical applications have always developed from experimental procedures. As a result of the ability to reach any portion of the jejunum, ileum or colon with reasonable ease, the intestinal chemistry, the motor activity of the bowel wall and the responses of the intestine to drugs came under investigation in man. Aspiration of the intestinal contents from chosen regions before and after specific foods has shown the site and rate of absorption, the range of intraintestinal osmotic pressure, the tendency of the chyme to approach neutrality and the mechanisms available to the intestine for maintaining these normal relations. Such data make possible the construction of good jejunal feeding mixtures. By attaching recording instruments to the lumen of the tube leading to the balloon and by injecting radiopaque mixtures locally into the lumen of the intestine, the movements of the intestine and their effects on the behavior of the contents have been determined. The projection of these studies into the clinical field has resulted in the diagnostic procedures to be discussed later. The pharmacologic action of drugs may be investi-

gated from the point of view of secretory, absorptive and motor phenomena in a manner impossible to accomplish in the surgically deranged digestive tract. Thus, from the experience accumulated in hundreds of experimental intubations, the therapeutic methods were developed.

### DIAGNOSTIC PROCEDURES

From these physiologic investigations have come both the diagnostic and the therapeutic procedures dependent on the passage of long tubes. The indications for diagnostic intubation are as follows: suspected absorption defects, such as those that appear to characterize sprue and allied conditions; mild abdominal pain in which the distinction between a neurosis and a small lesion of the intestine is difficult by other means; high-grade obstruction in which it is essential to know the location and nature of the obstructing lesion; and rare conditions, such as gastrointestinal hemorrhage of unknown origin or suspected intravisceral fistulas, when the aspiration of the contents of the intestine reveals the location of a lesion not otherwise detectable.

### Absorption Defects

The claim that a determination of intestinal absorptive power is of diagnostic value is as yet founded on somewhat tenuous evidence. It has long been believed that the group of diseases designated by such names as celiac disease, idiopathic steatorrhea, Gee-Thaysen disease and nontropical sprue is characterized by a loss of the specific absorbing power of the mucosa. The recent work of May and McCreary<sup>2</sup> has cast some doubt on this hypothesis, although the bulk of the evidence to date still supports the older point of view. If one is eventually to demonstrate the validity of

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1941. From the Gastrointestinal Section (Kinsey-Thomson Foundation), Medical Clinic, Hospital of the University of Pennsylvania.

†Assistant professor of medicine, University of Pennsylvania School of Medicine.

such a fault as an impediment to the patient's nutrition, one must be equipped with an accurate technic. Attempts have been made to appraise this by determining the blood levels of substances given by mouth. These measures have failed because, obviously, the blood level may be determined as much, or more, by the rate of elimination of the substance from the blood as by the rate of absorption from the intestine. One must then determine absorption by measuring the rate at which the test material leaves the intestinal lumen. Certain methods have been tried in the last few years, such as that of Groen,<sup>3</sup> which depends on the passage of a double-lumened intestinal tube, the distention of a terminal balloon and the retrograde filling of the intestine behind the balloon for a given period. Although this procedure suffices under most normal circumstances, the fact that conditions associated with poor absorption are usually accompanied by bizarre motility changes makes it practically impossible to prevent or to identify technical errors. A disappearance-time technic based on the qualitative testing of intestinal samples for glucose after the ingestion of a stated amount of sugar has been developed by Warren.<sup>4</sup> Noting the time at which the last trace of reducing substance disappears from the chyme gives a measure of the specific power of the epithelium to remove glucose. Although the experimental procedure of Zetzel and Banks<sup>5</sup> is excellent and could be applied as a clinical test, probably the most successful combination of simplicity with accuracy to date is the method of Nicholson.<sup>6</sup> This technic involves the passage of a triple-lumened tube 90 cm. beyond the pylorus, and the institution of a continuous flow of a 10 per cent glucose solution into the duodenum, with continuous aspiration of intestinal contents from a point above an obstructing balloon at the tip of the tube. A known length of intestine is thus continuously perfused with the test solution. The requirements of a good method are that it be simple enough to apply to sick patients, that a unit area of intestinal mucosa be examined, that the application of the glucose solution to the mucous membrane be quick enough to give a sharp starting time, that the residual glucose be removed from the test area at the end of the experiment rapidly enough to give a sharp stopping time, and that the mucosa be constantly supplied with a quantity of the test substance in excess of its maximum absorption capacity yet below a concentration level that would cause mucosal irritation and below a volume level that would grossly flood the intestine. By Nicholson's method, an initial acceleration of the intraduodenal flow can quickly

bring the solution into contact with 90 cm. of bowel, and the final introduction of a magnesium sulfate solution will wash out within two or three minutes the glucose remaining in the test region at the end of the absorption period. Although it is true that the balloon on the end of the tube continues to creep down the intestine at an unknown rate throughout the experiment, so that one ends a half-hour period with more mucosa exposed than at the beginning, the method as a whole is far freer from technical faults than any so far described. If one is to deal accurately with patients exhibiting clinical evidence of absorption defects, a diagnostic method that will unequivocally detect such faults becomes essential.

### *Organic versus Functional Lesions*

The second diagnostic use of intubation is the detection of minimal lesions masquerading as neuroses. This grew out of kymographic studies of intestinal movements. The balloon on the end of a long intestinal tube attached to a suitable recording instrument is a satisfactory apparatus for translating the contractions of the intestinal wall into a continuous graph on moving paper. A localized lesion in the small intestine practically always changes the character of the muscular contractions at that point, producing either local spasm or, if a long-standing partial obstruction has been present, local dilatation. The experience with this method is also too limited to permit dogmatic statements. Since the time for a record may occupy several hours, it may require several years to obtain enough normal control material. Nevertheless, the observations of Ingelfinger and Abbott<sup>7</sup> suggest that, in cases of midabdominal distress with functional symptoms and gastrointestinal x-ray series showing changes of doubtful significance, a balloon record will often tell, first, whether the intestinal disorder is local or general and, secondly, whether, if local, it is spastic or anatomic. From the therapeutic standpoint, this means the differentiation of a lesion possibly correctible by surgical means from one that should best be handled conservatively.

### *Injection of Opaque Mediums for Roentgenoscopy*

A far better established diagnostic use of intubation depends on the injection of an opaque medium.<sup>8-13</sup> This is an important supplement to the kymographic tracing of minimal lesions just described and has drawn the special attention of Boon.<sup>14</sup> A disorder may readily be sufficient to stop the advance of a balloon on a tube while still permitting the advance of a liquid such as a barium suspension. Thus, if during a diagnostic intubation the tube comes to rest at any given

point in the intestine, that region should be carefully examined fluoroscopically and with films during the injection of 50 cc. of a moderately thin water-barium mixture, and again half an hour after the injection, to determine whether the barium has advanced or remained at the point at which it entered the intestine. The fluid flows in the direction of least resistance, and retrograde regurgitation is the factor of chief importance in diagnosing obstruction. Distortion of the lumen, revealed by the advance of barium, may indicate the nature of the obstructing lesion. It should always be borne in mind that local spasm incident to contiguous disease, such as mesenteric lymphadenitis, may simulate a local lesion of the intestinal wall.

A far easier and probably more useful roentgen-ray diagnosis, however, is made by essentially the same procedure, carried out in the presence of complete obstruction. It is obviously unjustifiable to give a barium meal in the presence of a completely blocked intestine. In cases intubated for the relief of distention, it is proper, however, to inject barium down the tube for the detection of the exact site of the obstruction and for the determination of the nature of the lesion. If the block is complete, the injected barium is regurgitated proximally. It is becoming constantly more apparent, however, that decompression of such blockage usually renders the obstruction partial by the relief of local irritability, and improved nutrition aids by reducing the local edema. A little of the barium may therefore be massaged ahead of the tube, and the nature and the extent of the lesion be revealed. It is my opinion that this procedure should be routinely carried out preoperatively in such patients.

#### *Location of Rare Lesions*

Finally, there are those rare conditions whose diagnosis depends on the ingenuity of the physician almost as much as on his previous experience. When a patient bleeds by bowel in the presence of a negative barium enema and of an apparently normal stomach and duodenal cap, the chance of a benign tumor of the small intestine or a Meckel's diverticulum or even a bleeding polyp must be considered. If a tube is advanced continuously down the intestine until blood appears in the drainage, the balloon serves as a signboard to the surgeon, indicating the position of the lesion and making unnecessary the tedious palpation of the bowel that so often results in a stormy convalescence. In similar fashion, a variety of odd clinical circumstances have been clarified by the ability to reach points in the small intestine that were formerly not accessible.

#### Therapeutic Procedures

The therapeutic uses of the long intestinal tube must be considered. Some of these are so specifically surgical as to be out of the province of an internist. One may, however, suggest five chief uses: the prophylaxis against expected intestinal obstruction under unknown or complicated circumstances; the diversion of the intestinal current at a point proximal to the site of an anastomosis, as in surgery of the colon; the decompression of a distended and inactive intestine; the decompression of a distended and obstructed intestine; and the maintenance of nutrition and intestinal function during the course of local peritonitis with obstruction.

#### *Prophylaxis Against Intestinal Obstruction*

Under the head of prophylaxis against intestinal obstruction are included conditions that need only be mentioned, since they are frequently individual problems in themselves. Suffice it to say that in late cases of regional ileitis or in attempts to close traumatic fistulas a surgeon may sometimes anticipate a stormy convalescence before he begins the operation. A tube in the small intestine passed the night before may give him control of a postoperative condition that might otherwise determine a fatal outcome. Similarly, after a total colectomy, edema of the oversewn transverse mesocolon may compress the third part of the duodenum. Death has resulted when this has occurred in conjunction with delayed function of the ileostomy, since gastroduodenal drainage was useless. I now preoperatively intubate all colectomy patients.

#### *Protection of Intestinal Anastomoses and Colon Surgery*

Protection of incised areas of bowel during the postoperative period can be accomplished if a tube lies proximal to the suture line. In the performance of ileocolostomies and one-stage resections of the right side of the colon, much has been said of the importance of preventing colonic distention during the first postoperative days. Probably a more significant, though less obvious, cause of leakage is distention of the ileum proximal to the anastomosis. The patient may show no gross tympanitis because the volume contained within the ileum is relatively small, but for physical reasons the pressures developed are high compared with those in the colon. Thus, a little gas and fluid proximal to an ileocolostomy is far likelier to cause a leak than a large accumulation distal to the suture line.<sup>15</sup> Although decompression of the whole colon, allowing rectosigmoid resection without cecostomy, has occasionally been possible,

the protection of anastomoses is much more valuable.

This is the chief function of the intubation of the small intestine in one-stage resections of right-sided colonic lesions, and although the improvement in mortality statistics — such as 29 cases with 1 death reported by Ravdin and Abbott<sup>16</sup> and 53 cases with 2 deaths recorded by Whipple and Nelson<sup>17</sup> — cannot be attributed solely to the use of the tube, I consider it fair to say that it has been an important contributing factor.

### *Decompression of Paralytic Ileus*

Decompression of simple paralytic ileus, as distinguished from that associated with clinical peritonitis, is worth discussion. I am in complete agreement with Wangenstein<sup>18</sup> that the gas which distends these patients is very largely swallowed air, that the use of the Wangenstein tube for suction often prevents the occurrence of the condition if aspiration is started early enough, and that in mild cases it clears up the condition when once it is established. I disagree with him about the effectiveness of the Wangenstein technic in those cases seen after paralytic ileus has become extreme, with wide distention of the stomach, small intestine and colon, absent audible peristalsis, and the conditions attendant on marked abdominal distention. Whether these cases develop following intraperitoneal procedures or reflexly following injuries or operations on other parts of the body, a tube in the small intestine will progress from region to region, restoring peristaltic activity until the balloon is expelled by rectum. Because of the difficulty in determining when a case is severe enough to warrant intubation of the small intestine rather than the use of the Wangenstein tube, Pitressin, Prostigmine, choline derivatives, irritant enemas, stipes or rectal tubes, it is difficult to appraise the value of this procedure statistically.

Suffice it to say that 29 cases with 6 deaths have been reported by Penberthy, Johnston and Noer,<sup>19</sup> 9 cases with no deaths by Glenn,<sup>20</sup> and 55 cases with 5 deaths by Whipple and Nelson.<sup>17</sup> To these, I add my own experience of 16 cases with 3 deaths.

### *Decompression of Obstructed Intestine*

Decompression of the distention resulting from a mechanically obstructed intestine can be carried out by these tubes with a reduction in the mortality rate. Especially in this group, a careful selection of cases is essential. Suspected gangrene of the intestine, except in certain cases of mesenteric thrombosis, is always a definite contraindication to delaying surgery, and anyone undertaking to use intubation clinically must exert himself to perfect his ability to identify a strangulation. This diagnosis was of somewhat aca-

demic interest in the days when all cases of obstruction were immediately operated on, since the laparotomy promptly revealed the answer. Now that operation may be delayed for days, the patient's survival may depend on whether an impaired blood supply to the involved part is recognized. It is essential to remember that, when one is presented with a case of obstruction, the choice is not between intubation and operation, but between intubation and operation at that particular moment, and on each subsequent visit to the patient's bedside one must re-evaluate the indications for radical or conservative measures. Granting that strangulation is not present, it must be borne in mind that one is intubating for the relief of distention, a condition that, in the absence of strangulation, determines the high mortality in mechanical obstruction. If, therefore, distention does not exist, intubation is not indicated unless some other factor in the case justifies the procedure.

Patients who promptly present colic and hyperperistalsis, and in particular those with conditions giving circumstantial support to the diagnosis of simple obstruction, do not require the passage of a tube. It is in the late cases with marked distention, borborygmi, fecal vomiting, dehydration, electrolyte imbalance and shock — those patients who present on admission the worst surgical risk — that a method of improving the patient's condition before he is operated on becomes most imperative. This is the function of intubation. The tip of the tube advances down the intestine in spite of fecal vomiting until the obstruction is reached. The situation is then under control to such an extent that operation may be delayed for a day or a week or whatever interval is necessary to bring the patient into a sound state of nutritional balance. If the obstruction has not spontaneously subsided, and in certain cases even if this has happened, operation should be carried out.

Justification for this statement lies in the reports of 5 obstruction deaths out of 54 patients by Johnston, Penberthy, Noer and Kenning,<sup>21</sup> of 5 deaths out of 96 patients by Whipple and Nelson,<sup>17</sup> of 3 deaths out of 27 patients by Glenn<sup>20</sup> and of 5 deaths out of 74 patients in my own experience.

### *Relief of Peritonitis with Obstruction*

Finally, intubation enables one to control intestinal function and maintain nutrition in the patient with local peritonitis. Death from rupture of a gangrenous appendix or the spread of a pelvic peritonitis, even after the best surgery, is frequently the result of a combination of two main

factors the peritoneal infection, and the functional blockage of the intestine with uncontrollable distention and the starvation that results. When one controls the obstruction, distention and starvation, the patient, particularly with the aid of sulfonamide drugs, can frequently master his in

of the condition for which the patient is intubated.

Although the technic of intravenous alimentation is a godsend to all of us, it cannot be denied that the number of calories per twenty four hours that can be given by vein is hopelessly inadequate for long time maintenance, and it is frequently

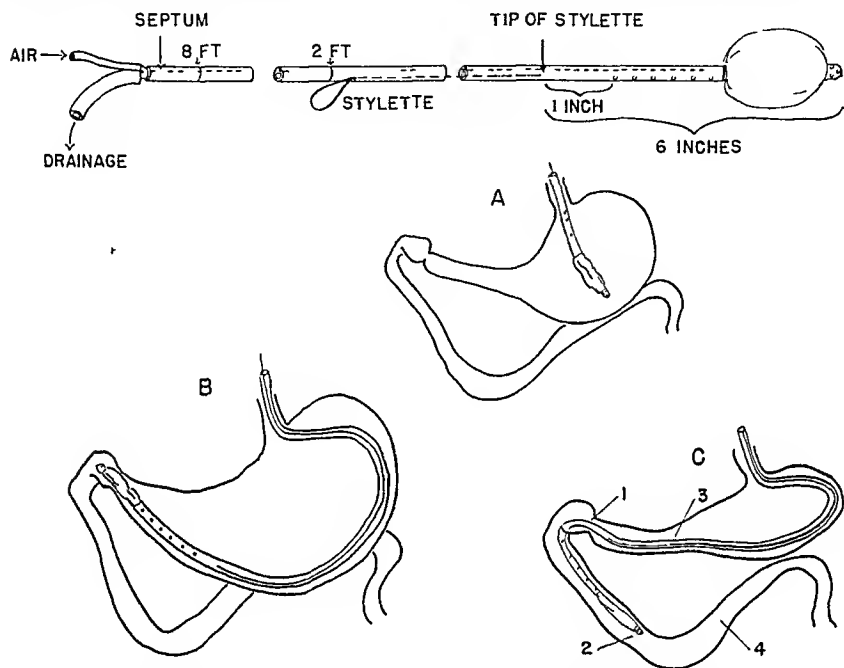

FIGURE 1 Technic of Using a Stylette in Passing a Miller-Abbott Tube

Pierce the wall of the aspirating lumen of the tube at the 50 cm (2 ft) mark with a length of 0.4 mm (0.016 in) diameter, specially straightened, stainless steel vom Hofe leader wire and advance the tip of the wire to a point 2.5 cm (1 in) above the most proximal aspirating hole in the tube. Bend a loop in the other end of the wire so that the tip cannot advance distally. The terminal 15 cm (6 in) of the Miller-Abbott tube will then contain no wire. Pass the tube in the usual manner to the position shown in A. With a temporary adhesive tape patch over the point at which the stylette pierces the tube wall, inject 300 cc of air into the stomach and advance the tube until it lies along the greater curvature, as in B. Hold the tube at the patient's nose to prevent its slipping out, and apply suction to remove the air. The stomach contracts, as in C, squeezing the tip of the tube ahead from position 1 to 2. The tip of the stylette then lies at 1. The antral spasm, with concentric contraction distal to 3, prevents the terminal 15 cm (6 in) from coiling, and the stylette prevents coiling of the tube proximal to the antrum, where the stomach is more flaccid. Draw back the tip of the stylette from 1 to 3, and by gentle, steady pressure on the tube at the nose advance the tip from 2 to 4. Withdraw the stylette, patch the hole through which it was introduced with thin rubber and, having inflated the balloon with 20 cc of air, proceed as usual.

fection. Such obstruction is as a rule self-limited and subsides in from one to three weeks under controlled circumstances. If it is necessary to keep an intestinal tube in place for that long, the question must be asked whether the risk of mucosal erosion by the tube at the larynx or farther down the intestine is greater or less than the danger

unbalanced from the nutritional standpoint. The opportunity given by the presence of the tube to feed a patient 1200 to 1500 calories of low-residue food daily by mouth while the residue is drawn off by the tube is therefore of great advantage. Frequently, after ten days or a fortnight or even longer of complete obstruction, the patient's bowels

begin to move, and intestinal function resumes its normal activity and maintains it after the removal of the tube.

The justification for the use of intubation in cases of this type is based on the report of 24 cases with only 6 deaths by Penberthy and his co-workers,<sup>19</sup> of 8 cases with only 1 death by Glenn,<sup>20</sup> of 92 cases with only 20 deaths by Whipple and Nelson<sup>17</sup> and of my own experience of 27 cases with only 6 deaths.

### TECHNIC

In addition to the indications for intestinal intubation, there remains the question of how to accomplish it. I know of general practitioners who are successfully and judiciously using this method; it is as a rule reserved not only for the hospital but for a physician on the hospital staff who is thoroughly experienced in the many difficulties and minor variations of the technic. If used without strict attention to detail, it is capable of causing great harm, and the interval throughout which one is entitled to persist in attempts to pass a tube rather than in carrying out surgical intervention must be determined in each case individually. This should not be determined by any set number of hours. It has been my own rule, so long as a patient is getting better rather than worse, to wait, irrespective of whether the tube is advancing well or not, but if the patient is getting worse rather than better, I advise operation regardless of what the tube is doing.

Recent developments in the technic have brought the speed of intubation far more directly under the control of the intubator. Following the basic principles laid down by Rousselot and Bauman<sup>22</sup> in 1933 for the use of a stylette in passing duodenal tubes, it has been possible to modify a stylette for use in long intestinal tubes (Fig. 1). With this instrument, one can usually bring the tip of the tube to the duodenojejunal junction within ten to twenty minutes. In a group of 18 severely ill patients with both obstructing peritonitis and mechanical obstruction, failure to accomplish this occurred in only 2. In the remaining 16, it was possible to pass the tip promptly to the distal duodenum, although previous experience had led me to anticipate that many hours would be required to do so. Since a stylette in a gastrointestinal tube is a potentially dangerous instrument, and since it is often far better for the patient if his stomach is thoroughly decompressed before the tip advances to the duodenum, the use of this procedure should not be routine. In the desperately ill patient, however, the ability to decompress the small intestine without delay may be crucial in determining the outcome.

### SUMMARY

Intubation of the small intestine was developed as a technic for studying the physiology of the digestive organs, and from the results have grown diagnostic and therapeutic procedures.

The diagnostic indications for intubation are aimed at the detection of disorders of absorption, minimal lesions ill defined by roentgenoscopy, advanced intestinal obstructions forbidding the use of opaque meals, and rare gastrointestinal disorders unidentifiable by standard methods of study.

The therapeutic indications for intubation are to forestall expected ileus incident to abdominal disease, to safeguard against leakage through intestinal suture lines, to abolish paralytic ileus, to control distention in mechanical obstructions, and to make possible the feeding of patients with peritonitis over long periods while the inflammation is subsiding.

The development of a stylette suitable for use in Miller-Abbott tubes has frequently made possible the prompt passage of the tip into the duodenum under the most adverse circumstances.

## THE DIAGNOSIS AND MANAGEMENT OF ACUTE OBSTRUCTION OF THE SMALL INTESTINE\*

LELAND S McKITTRICK, MD†

BOSTON

IF one excludes strangulated external hernias, the diagnosis of which is easy and the treatment obvious, the diagnosis and management of acute mechanical obstruction of the small intestine remain major problems of clinical surgery. Few questions have stimulated as much experimental work by excellent investigators as, 'What is the cause of death in acute small bowel obstruction?' Although this question has not been completely answered, from the results of these investigations have come certain basic facts that, when considered in the light of clinical experience, suggest a rational scheme for the management of these cases.

The development of such a plan presupposes an understanding of the significant clinical manifestations of the disease and of certain correlated experimental findings, as well as the ability to make a diagnosis.

### CLINICAL TYPES OF OBSTRUCTION

The clinical course of complete obstruction of the small bowel varies greatly, depending on the level of the obstruction and whether or not the obstruction involves the blood supply of the obstructed loop. An understanding of this problem is essential to proper management.

*Simple high obstruction*‡ (duodenal or high jejunal) is usually acute in onset. Vomiting of the juices of the upper gastrointestinal tract is early and profuse. The resulting dehydration is associated with rapid loss of electrolytes, of which the chlorides are the most important. A diminished urinary output and a rise in the nonprotein nitrogen of the blood follow, and there may or may not be an associated alkalosis. Such an obstruction runs a rapid course, in which distention is usually not a major factor, death in most cases results from a loss of essential body fluids. As a rule, early replacement of chloride loss by the parenteral use of physiologic saline solution or 5 per cent glucose in saline postpones or prevents death.

*Low ileal obstruction* is more complicated. The contents of the obstructed loop cannot be emptied

by vomiting. There is some absorption of the electrolytes above the obstructing point, so that the changes in the chemical constituents of the blood are neither rapid nor profound. The accumulation of fluid and gas in the obstructed segment results in increasing distention of the bowel. With the rise in intraluminal pressure, there is slowing of the circulation in the distended segment, congestion and edema of the bowel and, later, injury to the mucosa. It is probable that absorption into circulation ceases when the intraluminal pressure is sufficiently high. A replacement of chlorides in these patients does not materially influence the usual course of the obstruction. Some other factor or factors are responsible for death in these cases.

*Strangulation obstruction*, due to constriction of the mesentery of a loop of bowel and resulting in interference with its blood supply, regardless of the level of bowel involved, is a rapidly fatal condition, unless the constricting band is divided before irreversible changes take place in the bowel, or unless the devitalized bowel is removed from the peritoneal cavity. Death may occur from shock before development of the peritonitis that follows permeation of the devitalized bowel by intestinal organisms.

### DIAGNOSIS

The old teaching, 'Any patient with an abdominal scar and an attack of abdominal pain has an acute small bowel obstruction until proved otherwise,' should not be allowed to jeopardize those patients who have never been operated on but in whom such a condition may arise. Approximately 20 per cent of the patients seen at the Massachusetts General Hospital have had no previous operation.

The five important diagnostic criteria are as follows:

*Pain*, sudden in onset, severe and colicky in nature, usually at or above the level of the umbilicus but at times in the lower abdomen or generalized, is the presenting symptom in nearly every case of acute small bowel obstruction. This pain may be constant if strangulation is present or in the later stages of a simple obstruction. It may even disappear late in the course of the disease.

\*Presented at the annual meeting of the Massachusetts Medical Society on May 1, 1941.

†Associate in Surgery, Harvard Medical School; vs. M.D., surgeon, Massachusetts General Hospital; surgeon-in-chief, Palmer Memorial Hospital.

‡Simple obstruction means occlusion of the lumen of the bowel without interference with its blood supply.

*Vomiting* follows the pain. It may be small in amount or, in the later stages, copious and fecal in character. The so-called "fecal vomiting" frequently associated with intestinal obstruction is usually a late symptom and of no great help in an early diagnosis.

*Hyperactive, tinkling, high-pitched peristalsis*, audible over the abdomen, is often present, and although it is not necessary for a diagnosis, its presence is highly suggestive.

*X-ray evidence of one or more distended loops of small bowel*, as shown by a scout film of the abdomen, is the most useful single objective finding in a patient with small-bowel obstruction. The x-ray film should be taken after the stomach has been emptied of its fluid and gas content, and before an enema has been given. This avoids the confusing factors of gas and fluid in the stomach and the possible error due to the instillation of gas and fluid into the colon and its subsequent incomplete evacuation. I have observed dilatation of coils three hours after the onset of pain. On the other hand, I have seen two proved cases of obstruction during the past year (one with strangulation and the other a simple obstruction) in which there were no abnormal gas shadows. The inexperienced should be warned that the interpretation of existing shadows may be difficult. The small bowel may be so dilated that an x-ray diagnosis of large-bowel obstruction is made. In some cases in which the interpretation of gas shadows has been difficult, positive identification of the colon by injection of a small amount of barium by rectum has proved most helpful, and from this maneuver there have been no ill effects. In other cases, a repeat film after six hours may show a change in size or distribution of the gas which will facilitate a more accurate diagnosis.

*Constipation.* Characteristically, there is cessation of the passage of gas or feces by rectum following the initial pain. Small amounts of gas or feces may be passed, however, since in many cases the bowel below the obstruction empties itself of its contents. Moreover, the obstruction may at first be incomplete, and small quantities of gas may pass into the lower segment. Abdominal cramps with hyperactive peristalsis and little or no gas passing by rectum are strongly suggestive of an obstruction at some point in the intestinal tract.

*Strangulation obstruction.* When the diagnosis of small-bowel obstruction has been suspected or made, a more detailed interpretation of whether the obstruction does or does not interfere with

the blood supply to the obstructed loop is of the greatest advantage. In my experience, such a differentiation can readily be made in the later stages of the process, but only rarely in the early hours of the disease. Gangrene may develop very rapidly, as in a patient operated on six hours after the onset of symptoms and requiring resection of a gangrenous segment of bowel.

The pain in strangulation obstruction is usually steady, with or without associated spasms of colic. I have treated several patients with strangulation obstruction who complained of pain in the mid-back, a symptom not commonly encountered in the absence of interference with the mesenteric structures. Although tenderness may be present over the constricting point in simple obstruction, any increase or spread of this tenderness should be interpreted as evidence of strangulation, particularly if the tenderness is associated with muscle spasm. The leukocytic count is too uncertain to be of value. An abdominal tap is easily and safely done, and may prove useful in doubtful cases. A small-gauge hypodermic needle of adequate length or a 20-gauge or 22-gauge lumbar-puncture needle is used. The finding of blood-tinged fluid warrants a diagnosis of strangulation obstruction. A negative tap does not exclude it, however.

The diagnosis of strangulation obstruction is difficult to make early and costly to make late; it is therefore safer to operate promptly on all patients seen in the first twenty-four hours of their attack, since during this period, gangrene—whether incipient or actual—can usually be cured.

#### CAUSES OF DEATH

*Experimental.* Any attempt to review the experiences of the laboratories in the effort to determine the presence or absence of a toxic factor in death from simple obstruction of the small bowel would only confuse the clinician. However, from these laboratories have come many valuable facts that are accepted by most workers and are essential to an understanding of the treatment of these conditions. They may be briefly summarized as follows:

In simple high intestinal obstruction, death comes as the result of dehydration and chemical imbalance from loss of the juices of the upper gastrointestinal tract, whose replacement with physiologic saline solution prevents or greatly postpones a fatal outcome.

In simple low obstruction, other factors are involved, since replacement therapy does not greatly alter the length of life of such animals.

Distention is a constant and essential factor in the fatal cases without gangrene.

Distention is due primarily to gas—most of which is swallowed air—and intestinal fluid. Associated with or secondary to distention are marked increase in the bacterial count of the bowel content, diminution of the circulating plasma and blood volume, and slowing of the circulation in the bowel wall, with consequent interference with absorption and, later, injury to the mucosa.

Strangulation obstruction is associated with rapid and marked diminution of the circulating plasma and blood volume, and early injury to the bowel wall, with increased permeability to bacteria and ensuing peritonitis. Death follows in most cases from the effects of strangulation rather than as a result of the associated obstruction.

The dictum of the laboratories, therefore, is clear: lost chlorides should be replaced, distention should be relieved or prevented and in strangulation obstruction, lost plasma and blood should be replaced. If once, the strangulating mechanism should be relieved, and the necrotic bowel should be removed.

**Clinical** Whatever the lethal factors in experimentally produced obstruction may be, the fact

TABLE 1 Causes of Death in Acute Small Bowel Obstruction at the Massachusetts General Hospital 1924-1941

CAUSE OF DEATH	NO. OF CASES
Peritonitis	1
Pulmonary collapse or pneumonia	2
Shock	4
Miscellaneous	3

remains that 29 patients dying from acute small bowel obstruction at the Massachusetts General Hospital in the last seventeen years may be readily grouped under four different headings (Table 1).

All but 4 of these patients were operated on. In 3 (all with strangulation), the diagnosis was made at autopsy, and the fourth patient died of aspiration of vomitus during passage of a stomach tube. Eighteen of the 29 deaths were secondary to strangulation obstruction.

Not satisfactorily explained, either in the laboratory or from the hospital records, is the sudden collapse, usually fatal, that is occasionally seen following operation and the sudden release of a distended obstructed bowel either into the lower segment or externally.<sup>1</sup> Whatever its cause, it is a clinical entity that cannot be overlooked in the management of the distended bowel.

In a recent analytical study of 136 cases at the Massachusetts General Hospital,<sup>2</sup> certain pertinent clinical facts were re-emphasized.

Following the teaching that early diagnosis and operation are indicated on patients who are good risks, and relief of distention by simple blind ileostomy without exploration on those who are poor risks, the mortality in simple obstruction over a ten year period has been reduced from 31 to 12 per cent.\*

In 42 patients seen and operated on within twenty four hours after the onset of symptoms, there were no deaths, whereas in 17 patients entering within this period whose operations were delayed into the second twenty four hours,† 5 (29 per cent) died.

Fourteen (64 per cent) of 22 patients sixty years of age or older, and 6 (75 per cent) of 8 patients seventy years of age or more, died following operation.

Careful insertion of a No. 16 or 18 Fr catheter into a loop of distended bowel, using the Witzel or a comparable technic, without exploration of the abdomen, was a lifesaving procedure in late cases with marked distention. On the other hand, this same procedure in association with any attempt at exploration or manipulation of the bowel ended fatally, usually from peritonitis, in most patients so treated.

Thus, from a study of these records of patients, living and dead, it is apparent that prompt hospitalization, early diagnosis and early operation give good results, and that late diagnosis and early operation on a highly infected, distended or gangrenous bowel give poor results.

#### TREATMENT

From a knowledge of the foregoing experimental and clinical facts, the ideal treatment for acute intestinal obstruction can be readily formulated. In addition to prompt diagnosis and early operation (two or three hours after hospital admission) on all patients seen within twenty four hours of the onset of symptoms, immediate operation on any patient with strangulation obstruction should be performed. Substitution therapy, consisting in glucose in physiologic saline solution sufficient to restore lost electrolytes, should be instituted promptly. Prompt transfusion with plasma or whole blood into patients with marked distention or strangulation obstruction is indicated.

\*The increase in use of the early nasogastric tube and Wargens rectal suction undoubtedly contributed greatly to these results.

†Delay in these patients was due to inability to make a diagnosis of obstruction or because the condition was not considered as likely serious enough to warrant immediate operation.

Evacuation of the obstructed segment, to release distention, should be carried out before one attempts to relieve the obstructing factor in patients, seen twenty-four hours or more after the onset of symptoms, who have distended bowel on physical or x-ray examination.

The pioneer work of Wangenstein<sup>3</sup> on suction drainage of the upper gastrointestinal tract, given a new impetus by Miller and Abbott<sup>4</sup> and Johnson and his associates<sup>5</sup> by the demonstration of a practical method of draining the lower segments of the small bowel, has overcome the one difficulty—the relief of distended bowel in the patient with a simple but otherwise fatal obstructing lesion—in the application of the above principles to clinical medicine.

In November, 1939, the Committee on Small-Bowel Obstruction was organized at the Massachusetts General Hospital for the supervision and study of all such cases entering the hospital. This committee consisted of Dr. Richard Warren, the current residents on the two surgical services and myself. The actual treatment of the patients was carried out by the men on duty, as in the past.

Based on the principles outlined above, the following recommendations (previously expressed by two of the committee<sup>2</sup>) were given a trial:

Prompt replacement therapy is instituted for all cases and is continued according to the degree of chemical or fluid imbalance.

A double-lumened Miller-Abbott tube is passed immediately, and the stomach emptied of its fluid and gas contents. The patient is sent to the X-ray Department for a scout film, and an attempt is made to pass the tube through the pylorus at that time if evidence of small-bowel obstruction is present. If operation is to be done, suction is applied and maintained throughout the procedure to prevent regurgitation and possible inhalation of intestinal contents.

Operation is performed two or three hours after admission on all patients seen within the first twenty-four hours\* of the onset of symptoms, and on all patients with a diagnosis of strangulation.

Operation within six to eight hours is carried out in most cases seen in the second twenty-four hours after the onset of symptoms, except in patients sixty years of age or older and in those with marked distention.

Nonsurgical drainage is instituted for all patients sixty years of age or over who enter the

hospital twenty-four hours or more after the onset of symptoms, and in all patients whose symptoms are forty-eight hours† or more in duration.

If intubation is unsuccessful, if the patient is not relieved by continued aspiration of the stomach over a period of six to eight hours, if the degree of distention clinically or by x-ray study is not excessive, and if the patient is in good surgical condition, immediate laparotomy under general or spinal anesthesia should be performed.

If intubation is unsuccessful and if the age or condition of the patient or the degree of distention makes release of the obstruction hazardous, a blind enterostomy is done under local anesthesia. A catheter (No. 16 to 18 Fr.) is placed into a distended loop of bowel with aseptic technic and without exploration. If bloody fluid is found, the loop of gangrenous bowel must be found and delivered from the abdomen, regardless of the condition of the patient.

In good-risk patients, an operation of election should be done in those cases that have been successfully decompressed, regardless of whether the mechanism of obstruction has been outlined by the instillation of barium through the tube.

#### RESULTS OF TREATMENT

During the last eighteen months, 29 patients have been seen and followed by this committee. A correct diagnosis of strangulation was made once. It was not made but was present in 3 cases. Seven cases are excluded from this study because they were secondary to a carcinomatosis, pelvic infection or other conditions in which obstruction was only a contributory factor. Twenty-two cases of the type under discussion were seen. The number is too small to permit more than a report of progress, but these cases have been carefully studied, followed and reviewed at frequent committee conferences, and have been helpful in guiding us in the continued care of these patients.

*Diagnosis.* A correct diagnosis was made in 20 cases. Improper interpretation of scout films resulted in an incorrect diagnosis of large-bowel obstruction in 1 case, and 1 patient died of an undiagnosed strangulation.

Positive x-ray findings were present in all but 2 cases. The films in one of the positive cases were misinterpreted, and in another, an incorrect

\*The time limits set are of necessity somewhat elastic, but have proved to be of greatest help in deciding for or against early operation. It is only within the first twenty-four hours of the attack that most patients with strangulation can be saved, and that practically all patients with a simple obstruction can be safely operated on.

†Theoretically, all patients with simple obstruction not moribund on admission and without some serious constitutional disease should survive if properly treated. This is not so with strangulation obstruction unless the patient is operated on before irreversible changes have taken place (usually within twenty-four hours). After twenty-four hours have elapsed, 70 per cent of our patients with strangulation have required resection, with a mortality of 70 per cent. It is therefore safer to accept the hazard of strangulation than the risk of operation on the distended patient with a simple obstruction.

interpretation was made during the night by the Surgical Service and the roentgenologist on call, to be corrected the following morning by one of the senior members of the X ray Department. There is no question that the correct interpretation of these films is at times very difficult, but it is equally striking that without the use of a scout film the diagnosis could not and would not have been made in some of these patients. The 2 cases with no evidence of abnormal gas shadows are also of importance in indicating that negative x ray study must not be construed to exclude a diagnosis of acute obstruction.

**Miller-Abbott tube** A Miller-Abbott tube was passed in all patients but 2 infants with intussusception. As soon as the diagnosis was made, an effort was made with the fluoroscope to place the tube at or to pass it through the pylorus. In 10 of 20 cases, it did not pass the pylorus, owing in 3 cases to early operation, in 1 to spontaneous release of the obstruction, and in the 6 others to technical inability to get it through\*. It should be emphasized, however, that all these patients are benefited by the continuous aspiration of the stomach. I should probably be embarrassed to admit such a high percentage of failures, if I did not know that failure resulted only after a sincere effort by men of experience equal to that which I believe to be available in most well-organized hospitals. Because of this, 2 blind ileostomies were carried out successfully, one before and one after operation. Because of the difficulty of intubation, I believe that much valuable time may, but need not, be lost in prolonged unsuccessful attempts to obtain passage of the tube. This is particularly true in the earlier stages of the obstruction, when a corrective operative procedure can frequently be safely carried out.

**Mortality.** All but 1 of these patients were operated on, the exception being a seventy-two-year-old woman who responded well to suction drainage and whose age made elective operation inadvisable. There were no deaths from simple obstruction in this group of patients, although in 2 patients, both over sixty years of age, a note is made in the record that decompression by means of the Miller-Abbott tube (extending in one case for five days and in the other for eleven days) was life-saving. From a review of these cases, it is quite likely that had early operation been instituted, as the custom has been in recent years, death would probably have resulted in each case. Interestingly enough, were this so, the mortality in this small group would be the same as that for simple ob-

struction in the last decade at the Massachusetts General Hospital.

There were 4 patients with strangulation obstruction, 2 of whom died. One of them was a man of sixty-seven who entered the hospital acutely ill twenty-four hours after the onset of symptoms, on whom operation under local anesthesia was done in an attempt to save his life after all other efforts to improve his condition had failed. The second death was in an eighty-year-old woman who entered the hospital only seven hours after the onset of symptoms, who was followed for twenty-three hours after admission, whose x ray films showed no abnormal gas shadows, and who was finally operated on without a positive diagnosis, a strangulation obstruction requiring resection being found.

### SUMMARY

The important experimental and clinical evidence affecting the treatment of acute obstruction of the small intestine is summarized.

A working plan for the management of these cases is presented, and the results in a small group of 22 cases are reviewed. There were 18 cases of simple obstruction, with no deaths, and 4 cases of strangulation obstruction, with 2 deaths.

The value of early hospitalization and early operation in patients seen within twenty-four hours of the onset of symptoms is again emphasized.

## THE TREATMENT OF TETANUS\*

EARLE M. CHAPMAN, M.D.,† AND RICHARD H. MILLER, M.D.‡

BOSTON

THE treatment and nursing care of a patient severely ill with tetanus present a difficult medical problem. When we were faced with such an emergency, we turned to the literature for guidance but were disappointed by finding no adequate description of the clinical course of such a patient. Because of this apparent lack, we offer the following case report in detail, hoping that it may lend courage and help to those engaged in caring for patients with severe tetanus.

### CASE REPORT

B. M. (M. G. H. 258145), a 10-year-old boy, was running on the ocean beach on June 29, 1940, when he struck the side of his left foot at the base of the small toe. At first, this was thought to be a stone bruise, but the next day it was found that a splinter had penetrated the skin. The splinter was removed, and iodine applied; 3 days later he visited his family doctor, who advised hot boric soaks. By July 3, the area showed signs of inflammation and yielded a small amount of pus. The patient occasionally soaked the foot as advised but was active in play until July 5, when he did not feel well and complained of a backache at evening and passed a restless night. On the morning of July 6, he complained of headache, backache and a stiff neck. When seen at home at 11 a.m., he was in typical tetanus, with opisthotonos and risus sardonicus, and he had severe muscular spasms when touched. He was given phenobarbital and ½ gr. morphine, and transferred to the Massachusetts General Hospital at 1 p.m.

Sedation was started with 3 gr. sodium luminal subcutaneously, and at 2 p.m., under ether anesthesia, the area about the base of the little toe was excised and two black splinters of wood were removed. Cultures of these splinters, the longest 1 cm., yielded *Clostridium tetani*. An intracutaneous test with horse serum was negative. Although the patient's older brother was a known asthmatic, it was decided to give horse-serum tetanus antitoxin. He received 20,000 units of antitoxin about the wound, 20,000 units encircled about the left mid thigh and 20,000

units in an intravenous injection of 5 per cent glucose in physiologic saline solution. At 4 p.m., another 40,000 units of antitoxin was added to the fluid being given intravenously. A lumbar puncture was performed, and the fluid removed was replaced by an equal amount of fluid containing 10,000 units of antitoxin.

The patient remained under fair sedation, with a total dose of 12 gr. of sodium luminal subcutaneously and ½ gr. morphine in the first 12 hours. The back was arched, and he had intermittent, severe muscular spasms throughout the night.

A lumbar puncture at 10 a.m. on July 7 showed an initial spinal-fluid pressure equivalent to 400 mm. of water, which was reduced to 200 mm. by removing an opalescent fluid containing 1350 polymorphonuclear leukocytes per cubic millimeter; 50,000 units of antitoxin was given intravenously at 10 a.m., another 20,000 units at noon, and another 20,000 units at 3 p.m. The first severe convulsion came at 5 p.m.; fortunately, the resident physician was in the room and administered ether anesthesia and adrenalin. Several convulsions followed, and at 10 p.m. another lumbar puncture was done; again the initial pressure was 400 mm. and was reduced to 100 mm. by drainage of spinal fluid. An additional 10,000 units of antitoxin was given intravenously at 11 p.m. During the night, there were convulsions every 15 to 30 minutes, and the nurse administered ether and frequently aspirated the nose and the throat through the airway tube, which had been inserted at the time of the first convulsion. In this 24-hour period, the patient received 27 gr. of sodium luminal subcutaneously and also 7½ gr. of Sodium Amytal. Dressings of the foot wound with powdered sulfapyridine were done twice daily.

A severe convulsion at 7 a.m. on July 8 led to intense cyanosis, and oxygen, flowing at a rate of 4 liters per minute, was accordingly made available through a tube passed into the ether cone. At 8 a.m., another lumbar puncture was done, and the pressure was reduced from 350 to 100 mm. This definitely relieved the patient. Because of the sustained fever, the nurses—two special nurses worked together—applied to the trunk and extremities towels wrung out in cold alcohol; usually, 20 minutes of such application was sufficient to cause a drop of at least 2°F. in temperature. Throughout the day, his condition was poor, the respiratory rate and pulse increasing. At 4 p.m., convulsions began after an attempt to catheterize a very full bladder. The cyanosis and la-

‡Member, Board of Consultation, Massachusetts General Hospital.

bored respiration were helped by intravenous adrenalin, which was stopped when the pulse became rapid and feeble. At 9 p.m., a severe convulsion caused respiration to cease for 3 minutes. A lumbar puncture was done at 10 p.m., and the spinal fluid pressure was lowered from 300 to 75 mm., with definite relief. Ice packs were applied to the head at this time, and the patient seemed improved by these measures. In these 24 hours, he received 18 gr of sodium luminal subcutaneously—much of it at the discretion of the nurses.

On July 9, convulsions of moderate intensity continued about two in each hour, until 9 a.m., when another lumbar puncture was performed with considerable difficulty owing to the marked degree of opisthotonos. The intral pressure was found to be lower—250 mm. After drainage, with reduction of the pressure to 100 mm. the patient seemed easier, but respirations were rapid and considerable mucus in the air passages and in the airway led to the use of 1/100 gr of atropine subcutaneously in repeated doses. Because of the cyanosis and rather feeble and shallow respirations, all sedation was omitted. By afternoon, the patient seemed better, although edema of the extremities had appeared. By 8 p.m., respirations were stronger, and he occasionally sighed heavily. Cold packs were again administered, and there was a drop of 2°F in temperature.

Throughout the morning of the next day, the patient began to come out from under the previous sedation and convulsions returned in rapid succession. Cyanosis, labored respirations, made noisy by secretions in the bronchi and a pulse that was too rapid to count made us believe that he was in a very critical state. Sodium Amytal, 3½ gr every 3 hours, was resumed, and a transfusion of 500 cc of citrated blood was given slowly. Edema persisted and interfered with venipunctures. By evening, the patient was quieting down and seemed further improved after a lumbar puncture and drainage at 10 p.m., but an attempted intravenous injection again precipitated a severe convulsion. The total medication in these 24 hours was 22½ gr Sodium Amytal and 1/75 gr atropine.

On July 11, the convulsions lessened in duration and intensity during the day, and for the first time the nurses did not administer ether during the seizures. At noon the patient slept for 2 hours, and after this he passed gas and voided. Later, there were three convulsions that required the administration of ether. Edema continued so that 1000 cc of 5 per cent glucose in distilled water was given intravenously. Up to 9 p.m., 22½ gr Sodium Amytal and 1/100 gr atropine were given.

No sedative was given on July 12 until the patient suddenly had a severe convulsion at 8 a.m. This required ether. Several muscle spasms continued, and at 2 p.m. a lumbar puncture was done again and the pressure lowered from 200 to 75 mm., with immediate and striking improvement. No food or fluids had been taken by mouth up to this time, and at 10 p.m. the patient was therefore etherized and a nasal catheter passed through the left nostril into the stomach, hourly feedings of 45 cc of an equal mixture of milk and lime water were begun. Acidosis was suspected, but we were hesitant to find that the blood chloride was 99 milliequiv per liter (normal, 100 to 105 milliequiv), and the carbon dioxide combining power 24.3 vol per cent. The nonprotein nitrogen was 27 mg per 100 cc, the red-cell count 4,630,000 and the hemoglobin 15.6 gm. Throughout this day, the edema subsided, and the patient received 18½ gr Sodium Amytal and 6 gr sodium luminal after 8 a.m.

The next day was encouraging, since there were only

a few severe convulsions, and by evening there were only short spasms of the back, chest and leg muscles. The large amount of mucus in the throat and airway forced us to continue the use of frequent suction of the upper air passages and the repeated use of atropine. The total intake of milk and lime water by gavage was 1480 cc. Sedation totaled 11 gr of sodium luminal and 1¼ gr of Sodium Amytal.

On July 14, the patient seemed quieter until 5 a.m., when he vomited, became cyanotic and had a severe convulsion. The nurse then noted a diffuse, dull reddish, morbilliform eruption. The fever and respiratory rate increased, and the pulse could not be felt. The jaws were still tightly locked, and the body was becoming cyanotic. The situation was precarious and we feared that the patient would not survive the shock of serum sickness. At 11 a.m., we finally succeeded in completing a lumbar puncture, but we were surprised to find a normal intral pressure—150 mm. The only treatment through this period was continuous oxygen by nasal etherizer and repeated cold packs to the entire body. An intravenous injection of 500 cc of 5 per cent glucose in distilled water was given in the hope of preventing edema. Feedings of milk and lime water through the nasal tube were continued. Sedation in this 24 hour period was 11 gr sodium luminal and 7½ gr Sodium Amytal.

On July 15, the worst seemed over and by 3 a.m. the pulse was palpable. Cyanosis continued throughout the day, and the pulse became very thready in the afternoon, we therefore decided to transfuse him, 300 cc of whole blood plus 150 cc of saline being given. By 10 p.m., the patient looked better and breathed more easily, and the pulse was of better quality. A bloody nasal discharge began, and the nasal oxygen catheter was removed. He seemed weak and tired, and this was the first day without convulsions—there were only spasms of the muscle groups. The total sedation in these 24 hours was 12 gr sodium luminal and 3¼ Sodium Amytal.

On the following day, the nurses were encouraged, and for the first time admitted that the patient might recover. He was noisy, cried out, and had an excessive amount of bloody mucus in the upper air passages. There were no spasms from 3 until 10 p.m. A high-calorie feeding mixture was started, and he was given 30 gr chloral hydrate twice through the feeding tube. In this period only 3 gr of sodium luminal was given.

On July 17, the patient continued to groan and have muscle spasms, and the teeth could be separated about 10 cm. Frequent aspiration of the upper air passages was still necessary because of excessive mucus secretions. He was controlled with two 15 gr doses of chloral hydrate through the feeding tube and 30 gr once by rectum.

On July 18, fever and a bloody nasal discharge about the feeding tube, which had been in place for 6 days, caused some concern. It was removed, and careful aspiration, followed by argyrol in the nose, preceded its reinsertion through the right nostril. A furuncle appeared on the left shoulder, so that the patient was turned every hour. Throughout the day, he was restless, the eyes moved, and he cried out at 9 p.m., he first answered. Yes and squeezed the nurse's hand. The nasal tube was removed at 5 p.m., and from then until August 2 it was put down each morning for the gavage feedings throughout the day and removed about 9 p.m.

The patient continued to have spasms about every two or three hours on July 19, but he was slowly gaining consciousness and voided in the urine. He perspired freely, and mild dehydration was balanced with an intra

venous injection of 800 cc. of 5 per cent glucose in saline. The sedation in these 24 hours totaled 5 gr. of sodium luminal and 30 gr. of chloral hydrate by rectum.

On July 20, the condition was about the same, and the patient was trying to talk. Much mucus secretion was aspirated from the upper air passages. An abscess on the scalp was noted. The sedation was 12 gr. sodium luminal.

From July 21 to August 1, the chief problem was a sudden, rapidly spreading furunculosis and cellulitis of the head and neck. The scalp was shaved, individual abscesses were drained, and alcohol and iodine were applied thrice daily. This treatment was painful but effective, although a large cervical abscess had to be drained under ether anesthesia on July 28. Likewise, pressure areas on the shoulders and back demanded constant nursing attention. The amount of feeding by tube was gradually increased, and the patient tolerated high-calorie mixtures, orange juice and 20 mg. of vitamin B daily. On July 24 and again on July 30, a loose tooth was discovered and removed. On July 24, some concern was caused by signs of congestion in the right upper lung, and an x-ray film of the chest disclosed a small dense area in this region. This, however, rapidly cleared, and on July 30 the chest film was normal. There was no evidence of a fracture of the ribs or vertebrae. By July 27, the patient was able to swallow sips of water, but tube feeding had to be continued. From July 25 to 31, he was often disorientated, screaming and having hallucinations. Spasms of the muscles continued to keep the back arched, and we were unable to extend the legs completely. The sedation used in this period was chiefly sodium luminal subcutaneously, usually 3 to 6 gr. at night.

August 1 to August 29 marked the true period of convalescence in which each day showed a little gain in the general condition. August 2 was the first day in which the patient swallowed small amounts of soft food and could speak clearly but slowly. By August 5, he enjoyed having a book read to him for a short time. On August 6, another cervical abscess was drained, and on that day he listened to the radio and also fed himself.

On August 7, the red-cell count was 4,330,000, and the white-cell count 10,100. By August 14, the red-cell count had dropped to 4,000,000, and 4 gr. ferrous sulfate was given twice a day. On August 19, the first hour in a wheel chair caused a marked response, with fever, elevation of the pulse and fatigue. A swollen right axillary node began to cause pain and increased in size despite local applications of heat; on August 22, it was incised and drained. On August 27, the patient received 1.0 cc. of tetanus toxoid subcutaneously. After this, improvement was rapid, and he was discharged home on August 29.

On December 3, he was seen in the office and was given a second injection of 1.0 cc. of tetanus toxoid. At this time, he appeared entirely healthy and was mentally alert. He returned to school on January 6, 1941.

### DISCUSSION

Several features of this case warrant emphasis. The first is that the original injury occurred on the beach, an unlikely place for tetanus bacilli; one of us (R. H. M.)<sup>1</sup> had previously written that "ordinary wounds acquired in the home or in clean places, free from possible fecal contamination, or while bathing at the shore should not

require tetanus antitoxin." Obviously, we can no longer regard the seashore as safe from tetanus infection. As Moore and Singleton<sup>2</sup> have recently pointed out, this disease is present all over the United States, but its geographical distribution is highest in the South and least in New England. Despite this reassurance to those in the cooler climates, it is known that tetanus causes over a thousand deaths yearly in this country.

The second feature is that the onset of tetanus six days after the injury indicated a poor outlook. The direct relation between the incubation period and the mortality in this disease has been known since the time of Hippocrates, but the recent statistics of Kirtley<sup>3</sup> are of interest. He found that 72 per cent of those developing tetanus within ten days of the injury died in one to sixteen days; death followed in only 18 per cent of those developing it ten days or more after the injury. The short incubation period in our case is indicated in Figure 1.

In the treatment of this case, we employed six principles that we believe were of almost equal value in restoring this boy to health: profound sedation, surgical removal of the focus of tetanus, moderate intravenous dosages of tetanus antitoxin, frequent lumbar punctures, maintenance of adequate respiratory exchange and the most intelligent nursing care.

Adequate sedation is of utmost importance, and we agree with Spaeth<sup>4</sup> that enough sedation to relax the patient should be given before operating to remove the focus of tetanus bacilli. In this way, one avoids precipitating severe and possibly fatal convulsions early in the disease. The sedatives that we chose were sodium luminal, Amytal and chloral hydrate in large doses, but Evipal, Pentobarbital and others are probably equally effective. We believe that morphine and other respiratory depressants are contraindicated because death may occur from respiratory embarrassment. Likewise, we cannot recommend avertin, magnesium sulfate, paraldehyde or other drugs known to cause occasional constitutional reactions. Curare and similar substances are not yet generally available, although the use of curare has been reported by Cole<sup>5</sup>; evidently, its therapeutic and toxic levels are dangerously close to each other.

The second principle is the need for the complete surgical removal of the focus of infection, which can best be done under general anesthesia. The wound should be left open and allowed to heal from the bottom. The topical use of sulfa-pyridine or another sulfonamide is probably of value in sterilizing the wound.

A most encouraging and instructive experience comes from Africa, where Bryant and Fairman<sup>6</sup> observed that the natives demanding the same treatment for tetanus as for cerebrospinal meningitis were given lumbar punctures and enough Evipal to keep them anesthetized for three or four days. In these cases, tetanus antitoxin was never given, whereas in some of the later cases

It occurs to us that such a procedure should also delay the onset of serum sickness until the patient is better able to withstand it. In treating children, Dietrich<sup>7</sup> urges a slow but safe way to give serum antitoxin—the intramuscular route. Although our patient received an intrathecal injection of 10,000 units of antitoxin, it was done against the advice of one of us (R.H.M.). Since

FIGURE 1 Diagrammatic Summary of Data.

sulfapyridine was administered. Unexpected recoveries were made under this therapy, and in the last 22 cases so treated only 5 patients died, which is a lower mortality than most reported series from this country.

This experience of Bryant and Fairman throws into sharp relief the problem of whether to give antitoxin, and if so, by what route it should be given and the optimum amount to give. We advocate a moderate dose of the wound and intravenously with physiologic saline for the first few days of the disease. It seems unnecessary to give enormous doses, for it has been shown experimentally that if one full lethal dose has reached the spinal cord, a million neutralizing units of antitoxin do not save the animal.<sup>7</sup> The daily injection of 5000 units of antitoxin has been recommended by Firor<sup>8</sup> to ensure the maintenance of an adequate titer of antibody in the blood stream.

then, the reasons summarized by Hall<sup>10</sup> make this route seem quite inadvisable.

The next principle, possibly the most important one in our treatment, was the frequent drainage of spinal fluid. This procedure seems not to have been emphasized in previous reports. It is known that the cerebrospinal fluid is under an increased pressure during profound sedation and also during convulsive seizures; we therefore reasoned that lumbar puncture might bring relief to a patient in severe tetanus. The prompt alleviation afforded by these procedures seemed mechanical, allaying the nervous tension and convulsions.

The maintenance of a clear airway, an adequate supply of oxygen, the control of bronchial secretions and other measures such as the care of the skin, frequent turning, careful feeding by tube and the many details of the sickroom were largely the responsibility of the nurses.

Finally, we wish to direct particular attention to the use of tetanus toxoid. This should be used not only as a part of routine immunization in childhood but also at the time of injuries suspected of introducing tetanus bacilli. The occurrence of tetanus after the usual prophylactic dose of antitoxin is well known, and the recurrence of tetanus in the same patient has likewise shown that the disease itself may not confer immunity. Individual immunity may be linked to the occasional harboring of tetanus bacilli in the gastrointestinal tract, and it was the work of Ten Broeck and Bauer<sup>11</sup> that led to the suggestion that immunization could be established by the oral route. The use of toxoid, however, is far simpler and, according to Hall,<sup>12</sup> is completely safe if the toxoid is properly prepared. However, anaphylactic reactions, without fatalities, have been reported from England<sup>13</sup> as occurring twice in 64,000 men immunized for the Royal Air Force. It was found that these 2 persons were sensitive to the Witte's peptone used in preparing the toxoid.

Ramon, the discoverer of toxoid, has recently advised<sup>14</sup> the treatment of acute tetanus as follows: 2 cc. of toxoid subcutaneously and 150,000 units of antitoxin intravenously immediately, and then increasing doses of toxoid every five days, so that the patient receives 4 cc. on the fifth day, 6 cc. on the tenth day and so forth. Such treatment may be effective, but we remain convinced that the constant attention of the nurse and doctor and the employment of the six principles given here are essential to the recovery of the patient severely ill with tetanus.

### SUMMARY

A successfully treated case of tetanus, developing six days after injury, is described in detail.

Six principles of treatment that seem essential to recovery are discussed.

Recently, we have successfully treated another patient using these same principles. The summary of the case, reported through the courtesy of Dr. P. J. Shannon, of Hingham, Massachusetts, is as follows:

On May 27, 1941, a 14-year-old girl cut the dorsum of her right foot on a sickle that was rusted. She was seen within 10 minutes, and the wound cleansed with hydrogen peroxide and Merthiolate. Eight dermal sutures were used to close the wound. Three days later the wound discharged pus, and hot boric acid soaks were applied. On the 4th day fever developed, so sulfathiazole, 1 gm. every 4 hours, was given for the next 4 days. Hydrogen

peroxide dressings to the wound were continued; she seemed improved and was active.

On June 6, 9 days after the injury, she first developed trismus, and by evening she had back pains, headache and malaise; she was given 1500 units of tetanus antitoxin intravenously. The symptoms and signs of tetanus progressed through June 7, and on June 8 she was gravely ill and admitted to the Cohasset Hospital. In the next 24 hours she received 140,000 units of antitoxin intravenously and was given repeated doses of  $\frac{1}{2}$  gr. of morphine. At two periods in the late afternoon she became cyanotic and choked with mucus during the seizures. By evening of June 9, when first seen by one of us (E. M. C.), she was critically ill with severe tetanus and was having generalized spasms or seizures about every 3 to 5 minutes. Local tetanus also caused contractures of the right foot and leg. A culture of the wound was taken immediately and eventually yielded *Cl. tetani*.

Twenty thousand units of antitoxin was injected into three separate areas about the wound before it was debrided and left open. Sulfapyridine was dusted into the wound. Lumbar puncture was done, and dramatic relief of symptoms came after drainage of a clear fluid estimated to be under an initial pressure of 500 mm. Sedation was changed to sodium luminal, about 2 gr. subcutaneously every 3 hours. The nursing care was under the supervision of one of the nurses who had cared for the first patient.

In the subsequent 9 days in the hospital, this girl improved gradually. The lumbar puncture was repeated on June 11, with obvious relief of symptoms. The temperature fell slowly to normal from a level of 102 to 103°F., and the pulse declined gradually from a level of 120. By June 14, swallowing was less difficult and she had regained control of the sphincters. Tetanus toxoid was given as follows: June 12, 1 cc.; June 13, 2 cc.; June 14, 3 cc. Sedation was gradually reduced from a daily total of 16 to 6 gr. On July 18, for economic reasons, she was returned to her home for convalescent care.

## MEDICAL PROGRESS

### GENERAL ANESTHESIA\*

PRISCILLA SELLMAN, MD,<sup>†</sup> AND URBAN H. EVERSOLE, MD<sup>‡</sup>

BOSTON

**A**LTHOUGH inhalation anesthesia is usually considered synonymous with general anesthesia, other routes of administration of anesthetic drugs must be considered in a discussion of this subject.

#### RECTAL ANESTHESIA

Certain drugs are administered by the rectal route to produce general anesthesia. The most commonly used of these are tribromethanol (Avertin), paraldehyde and the barbiturate, Evipal. Of these, Avertin is probably the best known. These drugs are neither satisfactory nor safe when used alone, but are valuable as adjuncts to other anesthetic agents. They are useful as supplements to nitrous oxide and oxygen when a noninflammable inhalation anesthetic is desired. The administration of one of these drugs in the patient's room is often of great value in allaying the fears of nervous patients. Their principal disadvantages are that proper dosages cannot always be determined, owing to varying rates of absorption from the intestine, and that their administration is often followed by a prolonged period of depression. Because of the prolonged action of these drugs, respiratory obstruction is prone to occur during the postoperative recovery period.

#### INTRAVENOUS ANESTHESIA

The intravenous method of administration of anesthetic drugs has increased in popularity with the introduction of the shorter acting barbiturates. The most commonly used of these are Evipal Soluble and Pentothal Sodium. Their principal advantages are ease of administration and an accuracy of dosage comparable with that of the inhalation anesthetics. Furthermore, induction is usually rapid and pleasant, and recovery as a rule is free from such postoperative discomforts as nausea and vomiting. In common with the rectal anesthetic drugs, they are free from fire hazard.

On the other hand, the intravenous barbiturates have certain disadvantages of which the anesthetist should be cognizant before employing them as anesthetic agents. The margin of safety (the range between the anesthetic dose and the lethal dose) is relatively narrow. Reaction to comparable doses

varies widely, even among patients of the same age and of apparently equal vigor. Since these drugs are largely broken down in the liver and eliminated through the kidneys, they should not be used in patients with impaired liver function or uremia. Because of the means by which the barbiturates are eliminated, there tends to be an accumulation of the drug in the body during prolonged anesthesia. After the anesthesia has been carried on for some time, the addition of very small amounts of these drugs may push the level of anesthesia to a dangerous depth. Under intravenous barbiturate anesthesia, hiccups occur fairly frequently. This is a troublesome complication, the treatment of which is often quite unsatisfactory. The natural tendency when they occur is to increase the depth of anesthesia, this is usually ineffectual and may be hazardous. When anesthesia is light, laryngospasm is prone to occur if the larynx is irritated by operative manipulation or by secretions. For this reason, these drugs are usually not the anesthetics of choice for laryngoscopy and bronchoscopy. In patients with impaired kidney function, recovery may be somewhat prolonged. Finally, many patients, especially those in the elderly group, may be mildly disoriented for a period as long as twenty four hours after waking.

The intravenous injection of barbiturates must be done with care. If a 5 per cent solution of Pentothal Sodium is inadvertently injected into the subcutaneous tissues, marked irritation is likely to occur, and a solution as concentrated as 10 per cent may produce a severe slough. Furthermore, as pointed out by Lundy and Adams,<sup>1</sup> delayed phlebitis may follow the intravenous injection of a 5 per cent solution of Pentothal. For this reason, it is advisable to use a 2.5 per cent solution of this drug intravenously.

A simple and inexpensive apparatus has been described by Nicholson and Sise<sup>2</sup> for the administration of intravenous anesthetic agents. It consists of a small caliber, thick walled rubber tube about 75 cm. in length, with a glass observation tube on one end—to which the needle is fitted—and a stopcock with an adapter for a syringe on the other.

Intravenous barbiturate anesthesia is valuable for short operations when little muscular relaxation is required. It is particularly useful when

\*All articles in this series will be published in book form in the current volume of *Medical Progress*, Annual 1940 (Springfield, Ill. no. 5. Charles C. Thomas Company, 1941. \$4.00).

high-frequency electrosurgical apparatus is to be used or when the operative procedure is to be carried out in the x-ray room.

These drugs have recently been used as complements to spinal anesthesia. They should be used only for the comfort of the patient and never to augment a spinal anesthetic that is inadequate or has terminated; an inhalation anesthetic is preferable for this purpose.

#### INHALATION ANESTHESIA

Despite the increase in the use of other routes for the administration of anesthetic drugs, the inhalation method is probably still the most widely employed and the safest in general use, and is certainly the most flexible.

Most drugs used by this method are eliminated largely through the lungs, the liver and kidneys playing a minor part in their removal from the body. Increasing concentrations of the drugs in the blood bring about fairly well-marked changes in the character and rate of respiration, making guideposts by which the anesthetist may judge the depth of anesthesia. The flexibility of this method is such that an anesthetic course may range in depth from mere insensibility to complete flaccidity of most of the skeletal muscles, and in length from a fraction of a minute to many hours. Apparatus for the inhalation method may range from a handful of gauze and a container of anesthetic drug to the most complicated precision gas machines.

Today, although ether is still one of the most satisfactory and widely used general anesthetic drugs, there are many other well-established agents such as cyclopropane, ethylene, nitrous oxide and divinyl ether, which may be administered by the inhalation route, either alone or in combination with ether.

Divinyl ether has a rather limited use. It is a short-acting agent, and when given by the open-drop method is useful when abscesses are to be opened or packs removed or when other brief procedures are to be carried out. Prolonged divinyl ether anesthesia with inadequate oxygen may produce liver damage.

A new anesthetic agent, cyclopropyl-methyl-ether, has been introduced,<sup>3</sup> but its use is still in the experimental stage. Its sponsors state that it is more potent than ether and may possess many of the advantages of cyclopropane.

Cyclopropane, because of its many advantages, has attained great popularity in the few years it has been in use. In many ways, it can still be considered the closest approach to an ideal anesthetic agent that has yet been found. Its extreme potency allows for rapid induction and a very high

concentration of oxygen in the anesthetic mixture. The high concentration of oxygen reduces respiratory activity during anesthesia, but oxygenation has been shown to be adequate.<sup>4</sup> Its effects on the chemical constituents of the body are slight, and it is rapidly eliminated when the anesthesia is terminated.

Cyclopropane, however, has certain properties that prevent it from being an ideal anesthetic agent. Like many other hydrocarbons, it is inflammable. Unmixed with other anesthetic agents, it rarely produces the degree of relaxation required for abdominal surgery unless concentrations are used that are generally accepted as being outside the bounds of safety. Methods have been described and are in use in which concentrations as high as 75 per cent cyclopropane in oxygen<sup>5</sup> are delivered to the patient, and the subsequent apnea handled by artificial respiration or passive breathing. With this technic, the concentration of anesthetic drug is such that the respiratory center is itself anesthetized, and adequate oxygenation is maintained by the pumping of the anesthetic mixture into the lungs by the anesthetist. Relaxation is reported to be as complete as that obtained with spinal anesthesia, and although cardiac irregularities may be observed during induction, they are not found when the required depth of anesthesia is reached. This method is not in general use and seems to be more than a little hazardous except in the hands of those who are highly experienced with it.

Early in the use of cyclopropane, it was found that under fairly deep anesthesia cardiac irregularities developed in a certain number of patients. These are likely to occur with thyrotoxic patients and with those who have impairment of the mechanism of cardiac conduction. It was also found experimentally and, unfortunately, in the operating room that the injection of adrenalin into an animal or patient under cyclopropane produces cardiac irregularities and, in some cases, cardiac arrest probably because of ventricular fibrillation.<sup>6</sup> Laboratory studies on dogs have shown that the irritability of the automatic tissue of the heart is increased by cyclopropane and that morphine tends to increase this irritability further; the barbiturates decrease this tendency to cardiac irregularities to a point where, with deepening anesthesia, respiratory depression precedes their onset.<sup>7</sup> Similar laboratory studies have shown that procaine in small amounts, administered by the intravenous or intracardiac route, arrests the ventricular fibrillation that has been induced by superimposing adrenalin on cyclopropane, and restores normal rhythm.<sup>8</sup> Since procaine is extremely toxic intravenously, it is impractical for clinical use to

prevent cardiac irregularities. Although morphine seems to increase the tendency to cardiac irregularities, and occasionally to subsequent ventricular fibrillation in the dog, it is an extremely useful preoperative drug. Clinically, the barbiturates are not so satisfactory for preoperative medication when used alone as when combined with morphine. Preoperative medication appears to lengthen the margin of safety of cyclopropane by reducing the amount required to produce anesthesia without a comparable reduction in the amount necessary for respiratory arrest.

The majority of cardiac irregularities due to cyclopropane can be eliminated by lessening its concentration in the anesthetic mixture. However, it may be necessary to add another drug to maintain adequate depth. If care is taken that the cyclopropane concentration does not exceed 10 per cent, perceptible cardiac irregularities can usually be eliminated. If this concentration is inadequate to maintain anesthesia, ethylene or ether may be added as a supplement. When ethylene is used as the supplementary agent, the concentration of oxygen must be kept above 20 per cent, or else one of the advantages of cyclopropane, namely, a high concentration of oxygen, is eliminated. A combination of 60 per cent ethylene, 30 per cent oxygen and 10 per cent cyclopropane will give a mixture that is, in most cases, adequate for anesthesia and allows sufficient oxygen. Recovery when cyclopropane and ethylene mixtures are employed, seems to be as rapid as when either of these drugs is used alone.

Cyclopropane may be used instead of ether to supplement ethylene and oxygen or nitrous oxide and oxygen anesthesia. This allows for the administration of adequate oxygen at all times, in addition to the rapid induction and recovery characteristic of gas anesthesia. Although a mixture of ethylene and oxygen permits a somewhat higher concentration of oxygen (15 per cent or less) than that of nitrous oxide and oxygen (10 per cent or less), this is still too narrow a margin to ensure adequate oxygenation. This margin may be further narrowed if the patient has an increased metabolic rate. It must be borne in mind that the absence of cyanosis cannot always be taken to indicate adequate oxygenation.

Although a mixture of nitrous oxide and oxygen is usually inadequate to produce satisfactory anesthesia without suboxygenation, it has the advantage of being noninflammable. Combined with some nonvolatile anesthetic agent, such as intravenous Pentothal or rectal Avertin, it may be used with safety when x-ray or high frequency electrical apparatus is employed. This combination

also permits the use of the cautery about the head and neck.

The explosion and fire hazards present with most inhalation anesthetics are of sufficient importance to require special consideration. Precautions against these hazards should be most careful and painstaking. Ether, cyclopropane and ethylene, when mixed with oxygen, are potential bombs and should be handled with the same degree of respect.

Obviously, no open flames should be allowed in the operating room. If spark proof light switches and wall plugs are not available, all electrical connections should be made and turned on before the anesthesia tanks are opened, and should remain on until the anesthesia is completed and the machine flushed out with air. This flushing of the apparatus can be done by the anesthetist, blowing through the breathing tubes. Electrical equipment in the operating and anesthesia rooms should be carefully and frequently inspected by a qualified electrician. Electric motors and pumps should be placed outside the room when tanks of anesthetic gas are open. If high frequency electrical apparatus is to be used, ethylene, cyclopropane or oxygen and ether should not be administered.

Ether vapor mixed with air probably does not present so great an explosion hazard as ether vapor mixed with oxygen, ethylene and oxygen or cyclopropane and oxygen. Experiments done by Dr. J. W. King,<sup>9</sup> of the Massachusetts Institute of Technology, have shown that no mixture of ether and air will explode with the violence that some mixtures of ether and oxygen do or with the violence that all explosive mixtures of cyclopropane and oxygen do. However, when ether in air is being used in the presence of high frequency electro-surgical apparatus, special care should be taken to deliver the exhaled gases at a point several feet from the site of operation and from the electrical apparatus.

Despite the above precautions, the greatest source of ignition in the operating room, namely static electricity, still has to be dealt with. Obviously, the ideal method for dealing with this hazard would be for every piece of apparatus and all persons in the operating room to be electrically connected. This is not feasible at the present time. If the patient, anesthetist and apparatus (gas machine and operating table) nearest to the explosive anesthetic mixture are electrically connected, a great factor of safety is introduced.<sup>10, 11</sup> The Horton intercoupler\* is an apparatus de-

\*Manufactured by Technipment Company, Brockline, Massachusetts.

signed to connect electrically these four objects in the danger zone.

Inflammable gases should be given in a closed system with carbon dioxide absorption whenever possible, and the room should be adequately ventilated so that leakage of potentially explosive gases may be quickly dispersed. Some work has been done on the quenching value of inert gases such as helium<sup>12</sup> and nitrogen<sup>13</sup> on explosive gaseous mixtures. This may offer an additional safeguard; however, it is still in the experimental stage.

During the administration of a general anesthetic, attention to the maintenance of an adequate airway is as essential as the selection of the anesthetic agent. Nasopharyngeal and oropharyngeal tubes of various kinds relieve respiratory obstruction from the lips and tongue. Complete control of the patient's airway can be ensured only through the use of an endotracheal catheter. By this means, obstruction at the larynx is eliminated, and pressure on the trachea, especially in surgery about the neck, does not result in obstruction to respiration. By means of an endotracheal tube, obstruction from mucus, vomitus and blood may be avoided, since they may be removed by suction. The topical application of 10 per cent cocaine by means of an atomizer allows introduc-

tion of an endotracheal tube with the patient in a fairly light stage of anesthesia and eliminates considerable spasm and coughing when the tube comes in contact with the tracheal mucosa. In patients with marked tracheal obstruction, intubation may be done with topical anesthesia alone, and general anesthesia can be induced after the tube is in place.

CASE RECORDS OF THE  
MASSACHUSETTS GENERAL HOSPITALANTE MORTEM AND POST MORTEM RECORDS AS USED  
IN WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor*

## CASE 27431

## PRESENTATION OF CASE

A sixty-two-year old sheet metal worker was admitted to the hospital because of intermittent pain in the abdomen of one week's duration.

For the preceding six to eight years, the patient had been troubled with flatulent indigestion, mild constipation and aversion to fatty foods. On several occasions, he had experienced colic. Nine months before entry, he developed severe knifelike abdominal pain, accompanied by jaundice, and had been seen in another hospital, where cholecystectomy and exploration of the common bile duct were performed. The gall bladder was enlarged and thickened, and the common duct was found dilated, with a number of medium sized faceted stones in its distal end. The liver was described as "mottled." The convalescence was not remarkable, drainage being discontinued on the eighteenth day. The operation seemed to relieve the symptoms except for the intolerance to fatty foods.

Ten days before entry, closely following a meal of stewed chicken, a moderately severe aching pain spread across most of his abdomen. This pain was different from any that the patient had felt in previous attacks in that it seemed more constant and severer, and occurred lower in the abdomen. It continued with only slight remissions until entry. Three or four days before admission, there was gradual onset of jaundice. Increasing amounts of gas were passed by mouth and by rectum. The night before he came to the hospital, the patient vomited slate-colored fluid a dozen times, with some relief.

The past history was not significant. His first wife and his son by her had both died of tuberculosis.

On examination, the patient appeared acutely ill and definitely jaundiced. A right upper abdominal scar was present. The abdomen was tender, especially in the right upper quadrant. The liver was slightly enlarged and tender. External hemorrhoids were present. The only other positive findings were slight enlargement of the heart and

a few basal rales. The blood pressure was 198 systolic, 100 diastolic.

The temperature was 102°F, the pulse 70, and the respirations 30.

Examination of the blood showed a red cell count of 4,000,000 with 60 per cent hemoglobin, and a white cell count of 18,400. The van den Bergh reaction was biphasic, 11.1 mg per 100 cc. The blood sugar was 128 mg per 100 cc (148 mg when repeated). The prothrombin time was 26 seconds. The urine showed a +++ test for albumin, a +++ test for bile pigments and a trace of sugar, on repeated examinations. The stools were not reported.

A flat plate roentgenogram of the gall bladder region was negative. Duodenal drainage was performed, but no bile was found in the sample.

Operative intervention was deferred because of the patient's poor condition. The glycosuria and hyperglycemia were studied but no specific therapeutic measures were taken.

During the first few hospital days, the patient felt improved. The fourth day, however, his temperature rose to 106°F. The liver edge became much more tender, and jaundice deepened. There were no chills or flank tenderness. A roentgenogram of the chest taken in the horizontal position showed the diaphragm to be high, with poor aeration of the lungs. A three day course of sulfadiazine was given, following which the temperature dropped abruptly to 98°F. The drug was discontinued because of a fall in daily urine output to only 150 cc, accompanied by a rise in blood nonprotein nitrogen to 99 mg per 100 cc. The patient became progressively more jaundiced. He was given high carbohydrate therapy and intravenous amino acids. On the fifth hospital day, he vomited several times. Irregularity of the heart was noted. An electrocardiogram demonstrated auricular fibrillation, with a rate varying from 100 to 140 per minute, there were also irregular ectopic ventricular beats. Digitalis was therefore given, resulting in a return to fairly normal rhythm by the ninth hospital day. Four days later, the patient suffered a chill, and his temperature spiked to 104°F. During his last few days, the blood nonprotein nitrogen rose to 270 mg per 100 cc. This was thought to be due to the amino acid therapy he was receiving, since his urinary output had been restored. He became comatose and died on the fourteenth hospital day.

## DIFFERENTIAL DIAGNOSIS

DR. RICHARD H. SWEET: I remember this patient. He came in on the ward a day or so be-

fore I went off service. I do not know what the autopsy showed. He was under the care of Dr. John P. Stewart, who had charge of the cases of common-duct obstruction at that time. My only recollection is that he was exceedingly ill.

We are dealing with an obese, elderly man who was obviously in poor condition at the time of entry. The evidence for that seems to me to be, first of all, the albuminuria, which is also, perhaps, evidence of kidney damage. He may have had diabetes. He had cardiac enlargement with auricular fibrillation and ectopic beats. He had rales in the chest and definite anemia. The second fact that comes to the fore is that he had a known history of gallstones and stones in the common duct removed at operation. The third point I should like to bring out is that he subsequently had a characteristic history of common-duct obstruction, due most likely, I should think, to a stone left in the common duct at the previous operation. I say that because I happen to be a surgeon. The history is very typical. The patient was relieved for a time and felt all right, then had sudden onset of pain, and within a few hours, jaundice and obvious evidence of obstruction. If he had been my patient, I should have thought I had left a stone in the common duct. Secondary to this common-duct obstruction, the record shows evidence of infection of the biliary tract, with chills and fever, the so-called "Charcot syndrome." I should expect that he had cholangitis of an acute nature, with secondary liver damage.

Certain aspects of the case represent complicating factors, chiefly the therapy. One notes that sulfadiazine was given. Then, shortly after that, the sulfadiazine was omitted because of a marked reduction in urinary output and a rise in non-protein nitrogen. This may have been due to the chemotherapy. He may have had kidneys already damaged by arteriosclerosis. It is also known that people with this sort of liver disease do sometimes present evidence of renal damage presumed to be secondary to the liver insufficiency. The argument whether such patients die of liver disease or kidney disease is still a live one, in certain clinics at any rate. The other complicating factor is the amino acid therapy. I am not sure why amino acids were given. The record does not say whether the plasma-protein level was low, or whether he had generalized edema, suggesting perhaps nutritional lowering of the plasma protein; at any rate, he did have amino acid therapy, which I believe had been used very little up to that time on the service, and it probably did account for the marked rise of nonprotein nitrogen, if the

determination was made at the time that the amino acids were circulating in the blood. At that time, the urinary output was not low, and I should assume that the amino acids were not a factor in his death, although that possibility should be kept in mind. I see no evidence for any other conclusion than that he had choledocholithiasis, a stone presumably left in the common duct, in addition to infection, acute cholangitis and, perhaps, liver abscess. He must have had renal damage, whether on the basis of arteriosclerosis or not I do not know. I cannot go so far as to call this a case of hepatorenal syndrome.

#### CLINICAL DIAGNOSES

Cholangitis, acute.  
Multiple liver abscesses.

#### DR. SWEET'S DIAGNOSES

Choledocholithiasis, with obstruction.  
Acute cholangitis.  
Multiple hepatic abscesses?  
Renal damage.

#### ANATOMICAL DIAGNOSES

Cholangitis, with abscess formation and thrombosis of hepatic veins.  
Subhepatic abscess, probably at site of amputated gall bladder and cystic duct.  
Icterus, generalized.  
Pulmonary collapse and congestion, bilateral.  
Pancreatitis, minimal.  
Bile nephrosis.  
Decubitus ulcer, right buttock.  
Obesity.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: Some of the findings post mortem were quite obvious. The patient did have very extensive sepsis in the biliary tract, with a diffuse intrahepatic cholangitis and multiple liver abscesses. There was also a subhepatic abscess, in the immediate area of the removed gall bladder, a large, well-localized pocket of pus about the size of a distended gall bladder. There were no persisting stones in the duct; they had all been removed. The heart was somewhat hypertrophied, suggesting that he may well have had some hypertension and perhaps some renal insufficiency based on that, although the kidneys showed no striking degree of nephrosclerosis. At the time of autopsy, we were impressed with a little discoloration at the junction of the pyramids and cortex, which we thought might possibly be crystals of sulfapyridine, and in view of his terminal anuria we naturally attempted to establish that

point. We could not. There were no crystals, and I think the discoloration was due to bile-stained casts, rather concentrated at that point in the tubules. The kidneys were grossly swollen, and the cells of the convoluted tubules were likewise swollen and contained moderate amounts of bile pigment, the picture of what has been called bile nephrosis. That is something that one sees with considerable regularity in deeply jaundiced patients. So far as I can make out, its severity bears no correlation to the presence or absence of the so called "hepatorenal syndrome." I should be tempted to think that this man died from the combination of sepsis and hepatic insufficiency, and rather discount any renal factor, although on anatomic grounds it is impossible to do so with certainty. I should think that with such extensive liver disease as this, one ought to use caution in amino acid therapy. We know that amino acids are deaminized solely in the liver, and in the face of a nonfunctioning liver I do not see how the organism can dispose of them.

DR SWEET: It seems to me that that is the important thing about this case. As I read it over, I wondered what amino acids and the sulfadiazine had to do with his death. But he was an extremely sick man and probably would have died anyway of his underlying disease.

DR MALLORY: So far as the anatomical evidence goes, we can rule out the sulfadiazine as the cause of renal insufficiency.

## CASE 27432

### PRESENTATION OF CASE

A sixty two year-old housewife entered the hospital because of repeated episodes of pain in the chest.

Nothing was known about the first attack, except that the pain had been mild and had involved the left chest approximately six months before entry. The second episode, two months before admission, consisted in a moderately severe pain in the left chest accompanied by an ache in the left elbow. There was no radiation of pain to the shoulder, and there was no respiratory difficulty. The patient's physician prescribed a course of theobromine, potassium iodide and phenobarbital. At the time of this attack, the blood pressure was 164 systolic, 104 diastolic, the pulse 84, and the temperature 98.1°F. The following day the blood pressure was 140 systolic, 80 diastolic, the pulse 72, and the temperature 98.3°F. On the third day, the blood pressure was 130 systolic, 90 diastolic, and the pulse and temperature remained as before.

The patient was kept in bed for six weeks and then allowed up. The next day, she experienced minor chest pain. About ten days later,—ten days before entry,—pain again appeared, this time in the right chest, radiating to the shoulder and also across the abdomen. Three days before admission, there was an insidious onset of slight painless coughing. In the evening, a spell of severe coughing lasted six or seven minutes. During the night, the patient perspired freely and her heart seemed to "beat twice as fast as normal." The following day, she complained of a sensation "like a collection of gas" below the right breast, more disturbing when she coughed. Her local physician gave morphine and began a course of sulfathiazole.

The patient had had varicose veins for years and remarked that she had had a "sore spot" behind her left knee about ten days before she came to the hospital.

Physical examination showed an elderly and slightly obese woman, who was not acutely ill. She was pale, with cyanotic lips. Her respirations were grunting and cut short by pain, and there was definite splinting of the right chest. The breath sounds were diminished at the right base, with many crackling rales. The heart sounds were poor, although they seemed accentuated over the mitral area. The blood pressure was 120 systolic, 90 diastolic.

The pulse was 104, and the respirations were 28.

A roentgenogram of the chest showed the diaphragm to be high on both sides. In the left lung field, a band of density obscured the lateral shift of the diaphragm. On the right, there were numerous linear bands and some haziness just lateral to the hilus. The upper lung fields were clear, and the heart shadow was not displaced.

During physical examination, the patient suddenly turned ashen. Her lips became more cyanotic, and beads of perspiration stood out on her face. There was partial loss of consciousness. The respirations became more rapid. Morphine, atropine and Coramine were given, and the patient was placed in an oxygen tent. In the course of fifteen minutes, the respirations became slower and more shallow; death followed, an hour and twenty minutes after admission.

### DIFFERENTIAL DIAGNOSIS

DR RENO PORTER: Here is the case of a woman who, except for varicose veins, was in good health and feeling well until six months before admission. She subsequently experienced four attacks of chest pain. There were no other significant signs or symptoms, such as cough, respiratory dif-

ficuity and changes in pulse and temperature, and no change in blood pressure. The fact that the location of the pain varied from one attack to another tends to rule out many localized processes originating in the lungs themselves. The last attack was ten days prior to admission, when the patient also noted a sore spot behind her left knee. This is a very important point and gives some indication about the origin of most of her difficulties, namely, a phlebitis. However, one could suspect such an origin without this evidence, because pulmonary emboli usually occur repeatedly before the offending phlebitis becomes obvious. For three days before admission, the patient had symptoms indicative of pleurisy, with cough, splinting of the right side of the chest, pain on respiration and x-ray evidence of multiple lung lesions. Then she died abruptly, soon after she was admitted.

It is quite evident from the data presented that she had repeated pulmonary emboli. The terminal event was probably massive pulmonary embolism. I think one can conclude this from the repeated attacks of chest pain, a story quite characteristic of pulmonary infarction, and also from the fact that x-ray examination showed evidence of multiple lesions. One would, perhaps, like a little more evidence, such as symptoms and signs of respiratory difficulty, as well as temperature and pulse changes. They were not present, but their absence does not rule out the possibility, because embolism can occur without objective evidence.

The question in my mind is whether this entire story can be explained on the basis of pulmonary emboli. It has been generally assumed, and I for a time had the impression, that pulmonary emboli are nearly always secondary to something else, commonly following a surgical procedure or occurring as a complication of heart disease. Hampton and Castleman<sup>1</sup> have shown that this is not necessarily so by their study of 307 cases of pulmonary infarction. They found that in 30 per cent the patients were nonsurgical and noncardiac. This patient, we know, had not been operated on, so that there was no predisposing factor. The heart on physical examination was normal in size, with no significant murmurs. She did have hypertension, however. One cannot definitely rule out the possibility that one of these attacks of pain was coronary thrombosis. Her doctor apparently thought that she had had a coronary thrombosis, since she was kept in bed for six weeks. The onset of chest pain, however, is the only indication. There were no other striking signs or symptoms, nor is there an electrocardiogram to help us. There was apparently no significant

drop in blood pressure. The blood pressure fell somewhat in bed, but this could be explained by bed rest alone. There is very little evidence on which to make the diagnosis of coronary thrombosis.

Other conditions that might have occurred, such as infection, which her doctor suspected because he gave her sulfathiazole, need not be considered here. She did at one time complain that her heart beat more rapidly than normal. One must think of the possibility of an arrhythmia producing emboli that might go to the lungs. This tachycardia occurred during only one attack of pain, with no subsequent reference to irregularity. I think that this can be dismissed as a simple reaction to any insult to the lung.

I shall make a single diagnosis of multiple emboli. They arose probably from a thrombophlebitis of the popliteal vein on the left and possibly from the varicosities she had on the right. The emboli were multiple, and there should be infarctions of the lung, both old and recent. She may have had some pleural effusion on the right, associated with infarction, and I think she died of massive pulmonary embolism.

**DR. PAUL D. WHITE:** It is rare to find coronary episodes in the form of coronary thrombosis recurring repeatedly over a period of a few months. I therefore think that although pain was the characteristic symptom in the beginning in this case, the frequency of the attacks is very much against myocardial infarction as the explanation of the whole story. As Dr. Porter says, coronary thrombosis may have begun the sequence of events, but the later "heart attacks" were in all probability due to pulmonary emboli.

The hypertension we know very little about; there is simply a record of a blood pressure of 164 systolic, 104 diastolic, at the time of the attack. This may have been a rise, the result of pain or discomfort, but on the other hand, the pressure might have dropped to this level; so that myocardial infarction might have been present despite the relatively negative examination. We do not have a definite statement about the heart size, simply the signs; we should expect, however, that the x-ray report would have shown cardiac enlargement. Tachycardia is common in pulmonary embolism. It may be the only symptom of an attack of pulmonary embolism, and paroxysmal tachycardia may be wrongly diagnosed to explain such episodes as occurred in this case, which I think Dr. Porter has correctly interpreted.

#### CLINICAL DIAGNOSES

Recurrent coronary thrombosis.  
Pulmonary embolism.

## DR. PORTER'S DIAGNOSES

Thrombophlebitis, left popliteal vein  
Multiple pulmonary emboli.  
Pulmonary infarcts, old and recent  
Massive pulmonary embolism.

## ANATOMICAL DIAGNOSES

Coronary thrombosis.  
Myocardial infarction.  
Thrombosis of popliteal vein, left  
Multiple pulmonary infarcts.  
Acute massive pulmonary embolism

## PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN This patient had, as Dr. Porter predicted, numerous infarcts in the lung. They were present in every lobe of the right lung, more numerous in the lower lobe, and were of varying sizes and ages. There was no pleural fluid, but the pleura was fibrinous over the lower lobe. The main branches of the pulmonary artery were filled with emboli, and one large embolus was present in the right ventricle, extending through the pulmonary valve. The source of the emboli was in the left leg—the popliteal vein and many of its branches and tributaries were completely filled with thrombi. The heart weighed 375 gm. and showed slight hypertrophy. The coronary arteries showed severe sclerosis, with occlusion and narrowing. The left descending branch was almost completely occluded by a grayish thrombus, which might have been two or three months old. The anterior wall of the left ventricle was infarcted, and according to the criteria that were reported a few years ago by Mallory, White and Salcedo Salgar<sup>2</sup> on the various ages of myocardial infarcts, was about two months old. This would correspond with the second episode. I therefore suppose that the patient

started off, as Dr. White suggested, with a coronary thrombosis, was kept in bed for six weeks, allowing the peripheral thrombi to form while she was in bed, and when she got up developed a series of emboli and infarcts. Is it a general procedure to exercise the legs of patients with coronary disease?

DR. WHITE: Rest in bed for two months is much too long for the average person with acute coronary thrombosis and myocardial infarction, particularly because of the danger to the general health, especially from thrombophlebitis. There are, to be sure, some patients with congestive failure or other complications who may have to stay in bed longer, but as a rule, for patients with average-sized infarcts three or four weeks in bed are enough. Some have thought me unwise in advising such a short stay, but experience has confirmed its adequacy, in fact its preference. The chair position, incidentally, is better than the bed position so far as the heart is concerned. Instituting activity as soon as possible aids the peripheral circulation, as well as the morale and general health. I suppose we all tend to neglect to maintain adequate peripheral circulation in bed patients, which we can do by massage and even by active leg exercise. After the first two weeks, as soon as danger from the acute heart attack is largely over, the leg muscles need massage or exercise.

DR. HOWARD B. SPRAGUE: I have done that routinely for years. As soon as the fever is over, I start leg massage and encourage the patient to move the feet and wiggle the toes.

## ENCEPHALITIS AND THE HORSE

ONCE again, the importance of animal reservoirs of diseases affecting human beings comes to the fore. Recent work<sup>1-4</sup> from the West indicates that the virus of the St. Louis type of encephalitis is present in certain wild and domestic birds and mammals.

Especially in the group of encephalitides due to specific viruses has the role of animals become increasingly evident. About six months ago, Webster<sup>5</sup> pointed out that no less than nine distinct viruses—those of rabies, poliomyelitis, lymphocytic choriomeningitis, Japanese B encephalitis, louping ill, Australian X disease, virus B, equine encephalomyelitis and St. Louis encephalitis—are known to produce primary encephalitis in man.

At that time, there was good evidence of mammalian or avian host reservoirs for six of these agents. The virus of rabies was demonstrated in animals in 1881. During the last decade, the virus of lymphocytic choriomeningitis was found in the mouse, that of louping ill in sheep, that of virus B in the monkey, and that of equine encephalomyelitis in horses and birds. Furthermore, the serums of sheep and horses have been found to contain neutralizing antibodies for the virus of Japanese B encephalitis. All these diseases were thus linked with animals. Only three viruses—those of poliomyelitis, Australian X disease and St. Louis encephalitis—gave no evidence of potential animal reservoirs.

Now, however, the virus of St. Louis encephalitis, as well as that of the Western type of equine encephalomyelitis, has been incriminated in both horses and human beings in the Yakima Valley of Washington by the work of Hammon,<sup>1</sup> and in Weld County, Colorado, by that of Philip, Cox, Fountain and Kilpatrick,<sup>2,3</sup> of the United States Public Health Service. The presence of neutralizing antibodies in the serums of patients and horses indicated infection in some cases with one of these viruses, and in others with both. Similar evidence for mixed infection with the same viruses in human beings in California had previously been presented by Howitt.<sup>6</sup>

In the Yakima valley, the epidemics occurred during the two summers of 1939 and 1940. As might be expected in an outbreak due to two different agents, certain epidemiologic and clinical features were suggestive of each of the two types of encephalitis, although the general picture was more comparable to that of the St. Louis epidemic of 1933 than to any of the known equine-encephalomyelitis epidemics. Most of the patients lived near irrigation ditches or other potential sites of mosquito breeding. The possibility of insect vectors was not further investigated, but probable reservoirs for one or both viruses were suggested by the finding of neutralizing antibodies in the blood serums of a certain number of wild and domestic birds and mammals.

The reports from Weld County present similar

evidence of human infection with either one or both of these viruses. They further show that the serums of certain horses, not only from Colorado, but also from Montana and Washington, contained neutralizing antibodies for one or both viruses. The disease was reproduced experimentally in susceptible horses by the intracerebral inoculation of a proved strain of St. Louis virus. The resulting infection was indistinguishable clinically from that caused by the Western strain of equine-encephalomyelitis virus. It is thus evident that the differential diagnosis on clinical grounds is difficult, if not impossible.

Of even more interest, however, was the observation that during the course of this disease the infective agent was found in the nasal secretions but could not be detected in the blood. From the epidemiologic standpoint, therefore, it seems unlikely that transmission from the horse could be accomplished by blood sucking insects. Moreover, since the virus is present in nasal secretions, transmission may be possible by direct contact, by vectors such as the common housefly or horsefly, by fomites, by water and so forth. These findings obviously provide a fertile field for further research.

More recently Hammon and his co-workers<sup>7</sup> have isolated the viruses of western equine and St. Louis encephalitis from mosquitoes (*Culex tarsalis*) collected from areas in which human encephalitis cases occurred. This evidence suggests the vector. Several species of wild and domestic birds and mammals may then be the important host reservoirs,<sup>4</sup> whereas the horse remains only an accidental victim.

Effective therapy for these types of encephalitis is lacking. Specific therapeutic antiserums are of no avail at the present time because a sufficiently early etiologic diagnosis cannot be made. Prophylaxis with virus preparations, particularly for animals, offers some hope, but has not yet been investigated thoroughly enough. Particularly in view of the present defense program and the concentration of troops in camps, continued study of host reservoirs and methods of transmission is urgently needed to control these summer epidemics.

## MAN ON HIS NATURE\*

SIR CHARLES SHERRINGTON, the dean of British physiologists, and long the chief exponent of structural neurology, whose life has been devoted to the elucidation of the reflex actions of the nervous system in its component parts and the integration of this action in the brain, was a particularly happy choice as Gifford Lecturer at Edinburgh in 1937-1938. Who better than Sherrington could, to quote his own words, use natural science to provide a frame of reference for Natural Theology? With the outlook of a poet, he provides science's generalizations about nature, using as a comparison the ideas on the same subject of Jean Fernel, a French physician of the mid-sixteenth century, who wrote *On Hidden Causes* (Paris, 1542), the first modern textbook of physiology.

Sherrington first points out the great changes in science that have occurred in the four hundred years since Fernel's time. Dealing with hard facts, the mechanical behavior of electrons, for example, we hardly talk the same language or think and research with the same tools. Science still, however, deals with facts, and facts only—smaller and smaller, to be sure, but still concrete. We can look at nature only with them in mind, but since man is part of nature, we can also look at man, although with slight understanding. We see brain, cells and processes, and even diagrammatically satisfy ourselves regarding reflex action. But how can we envisage "mind"? Energy does not seem to answer the question. Sher-

\*Sherrington C S. *Man on His Nature*. The Gifford Lectures, Ed. N. Lush, 1933-1938. 413 pp. New York: The Macmillan Company, 1941.

Sherrington concludes that "mind" for anything "... perception can compass goes therefore in our spatial world more ghostly than a ghost. Invisible, intangible, it is a thing not ever of outline; it is not a 'thing.' It remains without sensual confirmation, and remains without it for ever. Stripped to nakedness there remains to it but itself. What then does that amount to? All that counts in life. Desire, zest, truth, love, knowledge, 'values,' and, seeking metaphor to eke out expression, hell's depth and heaven's utmost height." To this concept of "mind," Sherrington adds "the perceived world. . . . Together they make up the sum total for us: they are all we have."

This, and much more, will be found in this thought-provoking book, a scholarly treatise such as is rarely given to the world. Not by any means easy reading, it will provide rich nourishment, if slowly digested. In a busy, war-torn world, too few will have time for such an intellectual treat; but *Man on His Nature* will last, and no doubt will be read four hundred years from now, just as Sherrington reads Fernel's *On Hidden Causes*.

## MEDICAL EPONYM

### KORSAKOW'S SYNDROME

Sergei S. Korsakow (1853-1900), privatdocent of the Imperial University in Moscow, described the syndrome that bears his name in an article entitled "Ueber eine besondere Form psychischer Störung, combinirt mit multipler Neuritis (A Peculiar Form of Psychic Disturbance Associated with Multiple Neuritis)" in the *Archiv für Psychiatrie und Nervenkrankheiten* (21: 669-704, 1889). He refers to his first report on the subject, which appeared in a Russian journal, *Westnik Psychiatrii*, during 1887 under the title, "Disturbances in the Psychic Sphere Occurring in Alcoholic Paralysis, and Their Relation to the Psychic Disturbances in Multiple Neuritis of Nonalcoholic Origin." A portion of the translation follows:

This psychic disturbance is shown sometimes in the form of a well-marked irritable weakness of the psyche, sometimes in the form of confusion, with quite characteristic disorientation in regard to place, time and situation, again as an almost pure variety of acute amnesia, with the most extreme sort of disturbance in the memory for recent events, while remote occurrences are well remembered. This unique psychic change is almost constantly present to a greater or less degree in the multiple neuritis of alcoholic patients; it

is not, however, an exclusive characteristic of alcoholic neuritis, but also occurs in neuritides due to a variety of other causes.

## MASSACHUSETTS MEDICAL SOCIETY SECTION OF OBSTETRICS AND GYNECOLOGY\*

### FATAL SHOCK, FOLLOWING PLACENTA PREVIA AND MASSIVE HEMORRHAGE

A thirty-six-year-old para X entered the hospital, when approximately seven months pregnant because of a sudden massive hemorrhage.

The patient had eight living children, and she had been one miscarriage. The last pregnancy was terminated by a cesarean section, and a living child weighing 9 pounds, 9 ounces, was delivered. The section was indicated because of an amputated cervix, and the repair of a third-degree tear of the perineum.

The patient had bled a little several times during the previous two months. Two weeks before admission, she had bled sufficiently so that a diagnosis of placenta previa was considered, although no vaginal examination was made. An x-ray film taken for the purpose of diagnosis did not show a placenta previa. On the day of admission, the patient had a very sudden massive hemorrhage at home and was sent to a hospital, where a vaginal pack was inserted. From this hospital, she was transferred to another institution, where the first pack was removed and a second introduced; a central placenta previa was found. Because the bleeding was excessive, cesarean section was performed immediately. A living child was delivered but died shortly after birth. The patient died four and a half hours after operation. The patient was apparently not transfused; the record states that she died of shock.

*Comment.* From the obstetric point of view, this patient was not ideally handled, and the fatal result should have been averted. Any patient who bleeds in the last trimester is entitled to an intelligent search for the cause of the bleeding. No intelligent diagnosis can be made without a vaginal examination. This patient was seen several times because of this bleeding, but at no time was a vaginal examination made. Had one been made and the cervix investigated, the central placenta previa would have been diagnosed, and the operation might have been done at election, not when the patient was weakened by excessive hemorrhage.

\*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters should be addressed to Dr. Raymond S. Titus, Secretary, 330 Dartmouth Street, Boston.

and in moderate shock. X-ray study in the diagnosis of placenta previa is not always reliable; it should never take the place of a thorough and intelligent vaginal investigation.

The previous cesarean section made a second section imperative. No patient is so badly off that transfusion before operation is not of inestimable value, because any patient who succumbs while being transfused certainly would not survive, no matter what was done to her. It is barely possible that immediate transfusion, followed by operation, might have tided her over, but this is only problematical.

The lesson to be learned from this case is that all patients with bleeding in the last three months of pregnancy should be hospitalized, a definite diagnosis of the cause of bleeding made by vaginal examination, even at the expense of invading the cervical canal, and subsequent treatment based on this diagnosis given at the time of election. It is routine in most obstetric institutions that, when a vaginal examination is attempted on bleeding cases of this sort, a bagging kit and a laparotomy kit are both in readiness and an acceptable donor is at hand. It is only by following this technic that such fatalities can be averted.

## DEATHS

**BURNS**—HIRAM H. BURNS, M.D., of Plymouth, died May 10. He was in his eighty-sixth year.

Dr. Burns received his degree from the Harvard Medical School in 1887 and was a fellow of the Massachusetts Medical Society and the American Medical Association.

His widow survives him.

**KRANTZ**—MICHAEL KRANTZ, M.D., of Quincy, died September 4. He was in his sixtieth year.

Born in Russia, he received his degree from Middlesex University School of Medicine in 1921. He was a fellow of the Massachusetts Medical Society and of the American Medical Association.

His widow survives him.

**MURPHY**—DANIEL D. MURPHY, M.D., of Amesbury, died August 8. He was in his seventy-eighth year.

Dr. Murphy received his degree from the Dartmouth Medical School in 1891. At the time of his death, he was on the staffs of the Anna Jaques Hospital, Newburyport, and the Amesbury Hospital. He was a former president of the Essex North District Medical Society, and was a fellow of the Massachusetts Medical Society and the American Medical Association.

His widow and two sons survive him.

## MISCELLANY

### RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR AUGUST, 1941

DISEASE	AUGUST 1941	AUGUST 1940	FIVE YEAR AVERAGE*
Anterior poliomyelitis	45	9	36
Chicken pox	125	81	105
Diphtheria	6	12	14
Dog bite	1043	1178	1112
Dysentery, bacillary	30	15	14
German measles	31	20	24
Gonorrhea	283	366	457
Measles	282	506	277
Meningitis meningococcal	4	3	5
Meningitis, other forms	4		
Mumps	274	157	137
Paratyphoid fever	8	36	17
Pneumonia, lobar	74	91	110
Scarlet fever	196	77	110
Syphilis	341	297	415
Tuberculosis, pulmonary	281	298	301
Tuberculosis, other forms	26	25	31
Typhoid fever	9	11	11
Undulant fever	13	1	4
Whooping cough	575	505	511

\*Based on figures for preceding five years

### GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Actinomycosis was reported from: Malden, 1; total, 1.

Anterior poliomyelitis was reported from: Beverly, 1; Boston, 4; Brockton, 3; Cambridge, 4; Dudley, 1; Leominster, 1; Fairhaven, 1; Haverhill, 2; Lawrence, 1; Lynn, 2; Malden, 1; Melrose, 1; Methuen, 5; New Bedford, 9; Northbridge, 1; Provincetown, 1; Quincy, 1; Somerville, 1; Taunton, 1; Uxbridge, 1; Wareham, 2; Worcester, 1; total, 45.

Anthrax was reported from: Peabody, 1; total, 1.

Diphtheria was reported from: Fall River, 5; Wrentham, 1; total, 6.

Dysentery, amebic, was reported from: Fitchburg, 1; total, 1.

Dysentery, bacillary, was reported from: Boston, 1; Braintree, 1; Cambridge, 1; Danvers, 7; Ipswich, 1; Melrose, 1; Medford, 1; Stoneham, 1; Watertown, 1; Worcester, 15; total, 30.

Infectious encephalitis was reported from: Cambridge, 1; Fall River, 1; New Bedford, 1; total, 3.

Malaria was reported from: Framingham, 1; total, 1.

Meningitis, meningococcal, was reported from: Cambridge, 1; Stoneham, 1; Wareham, 1; Yarmouth, 1; total, 4.

Meningitis, other forms, was reported from: Arlington, 1; Boston, 1; East Bridgewater, 1; Weymouth, 1; total, 4.

Paratyphoid fever was reported from: Beverly, 1; Cambridge, 1; Fort Banks, 1; Ipswich, 1; Lynn, 1; Medford, 2; Peabody, 1; total, 8.

Pellagra was reported from: Boston, 1; Peabody, 1; total, 2.

Septic sore throat was reported from: Boston, 1; Cambridge, 1; Greenfield, 1; total, 3.

Tetanus was reported from: New Bedford, 1; total, 1.

Trachoma was reported from: Fall River, 1; Nauck, 1; total, 2.

Trichinosis was reported from: Boston, 1; Worcester, 1; total, 2.

Typhoid fever was reported from: Ayer, 1; Boston, 4; Deerfield, 1; Fall River, 1; Marblehead, 1; North Adams, 1; total, 9.

Undulant fever was reported from: Brookfield, 1; Deerfield, 1; Falmouth, 1; Franklin, 1; Haverhill, 1; Hopkinton, 1; Leominster, 1; Medford, 1; North Adams, 1; Orange, 1; Sheffield, 1; Uxbridge, 1; Worcester, 1; total, 13.

For the sixth consecutive year anterior poliomyelitis failed to reach epidemic proportions by the end of August.

Undulant fever was at a high level during the month.

Mumps and meningococcal meningitis both tended toward higher levels, though they have shown the usual seasonal decline.

Chicken pox, bacillary dysentery, scarlet fever and whooping cough were slightly above the five-year average. Diphtheria, lobar pneumonia and typhoid fever were at unusually low levels.

Dog bite, gonorrhea, paratyphoid infection, syphilis and pulmonary tuberculosis were reported below the five-year averages.

Measles and German measles, which showed increased prevalences earlier in the year, made a rapid seasonal decline.

### X-RAYING MILITARY MEN

Experience in World War I showed the value of discovering tuberculosis among military men. When the Selective Service Act went into effect, the Navy was requiring a chest roentgenogram for all enlisted and commissioned men, and the Army for the commissioned personnel only; facilities for routine roentgenography of all men were not at first available. Among the civilian agencies that supplemented the efforts of the Army in this emergency was the Bureau of Tuberculosis of the New York City Department of Health. These abstracts are taken from a record of that organization's experiences (Edwards, H. R., and Ehrlich, D. Examinations for tuberculosis, *J. A. M. A.* 117:40-45, 1941).

An order issued October 28, 1940, by the Adjutant General's Office of the United States Army made it possible for civilian organizations to set up a roentgenographic service for men inducted into the Army. It provided for payment for x-ray films and for the services of civilian roentgenologists (under due control) until such time as the Army could assemble its equipment and assume full responsibility.

The Bureau of Tuberculosis of the New York City Department of Health has been engaged in mass roentgen-ray surveys of the apparently healthy population since 1933. These surveys have been accepted as a basic part of the tuberculosis-control program of New York City, and thus interest, based on experience, in providing a similar service for inductees and members of the State National Guard was keen. Accordingly, the bureau's mass roentgen-ray services, which were made possible through the WPA, were offered to the Surgeons of the Second Corps Area prior to the Adjutant General's order. Financial assistance was received from the tuberculosis associations of Queens and the Bronx.

After January 1, 1941, the Army assumed full financial responsibility for the roentgen-ray service in induction centers. The Department provided personnel for the interpretation of films. Since January 15, this service has also been taken over by the Army, which has assigned medical reserve officers qualified in this special field. The roentgenographing of National Guardsmen has been entirely at the expense of the Department of Health. Under existing regulations, the Army could not pay for this service until after induction, and it was essential that rejections be made before induction.

At the outset, there were four induction stations. Since January 1, 1941, all work has been done in two stations, one in Manhattan and one in Queens.

Those rejected men who were residents of New York

City were given an appointment within the next two or three days to appear at the Health Department's Central Chest Clinic, where a complete study of the case was made. If this examination proved the original findings to be of no significance, the local draft board was so notified.

Rapid roentgenographic service was necessary, since the recruit was supposed to be cleared through all examinations by 2:30 p.m. of the day he reported at the induction station. With from 60 to 300 men per unit to be handled daily, even the rapid roll method used in the routine survey program was inadequate. Consequently, a special type of apparatus was devised. A modification of the roll paper camera was used in connection with a specially constructed portable dark room measuring 8 by 8 feet, with the back of the camera integrated into one side of the dark room. A signal device was installed between the roentgen-ray technician and the dark room. As soon as a film was exposed, the signal was flashed, and the dark room crew cut off the film and placed it in the developing bath. The signal was then reversed, indicating that another film was ready to be exposed. A team of three, consisting of a technician and two dark-room assistants, were able to operate faster than one exposure a minute. The films were processed in large trays and from the fixing bath were passed out to the physician through a light-proof pass. After being read, the films were washed in a portable tank and dried in a special device designed for the purpose.

Acceptance or rejection was based on Army regulations. Men showing any form of reinfection types of tuberculosis were rejected, because lesions of such types may become aggravated under conditions of military service. Primary lesions considered as active or extensive calcifications were likewise cause for rejection. Other forms of significant pulmonary disease, such as bronchiectasis, pneumonitis, atelectasis and extensive pleural changes, were cause for rejection until further study could determine their importance. Men with obviously abnormal cardiac silhouettes were reported to the medical examiners for such further study as might be indicated. Men with nothing more than apical caps, and those with small well-healed primary lesions were not rejected.

The group of men examined up to January 15, 1941, a period in which the Department of Health was actively engaged in the program, included 6609 inductees and 9541 guardsmen, a total of 16,150 who were x-rayed.

Of the inductees, 1.36 per cent were rejected and of the guardsmen, 1.21 per cent. About one third of the guardsmen were below the age of twenty-one, whereas only about 0.5 per cent of the inductees were below that age. An all-Negro regiment (National Guard unit) had the highest mean age in all groups and the highest rate of rejection, which was almost entirely on the basis of pulmonary tuberculosis. If the findings in this unit are subtracted from the totals of all National Guard units, a greater difference will be found between guardsmen and inductees.

Classification by stages of disease of the 70 men whose lesions were considered clinically significant shows that 65.7 per cent were minimal, 32.9 per cent moderately advanced and 1.4 per cent far advanced. Primary lesions indicated by calcific deposits were found in 6 per cent of the white men, 8.7 per cent of the Negroes and 7.1 per cent of the Puerto Ricans.

The group of men examined since January 16 and through March 31, 1941, totaled 35,210 men. During that period, the Department of Health's part has been

to re-examine and classify New York City men rejected at the induction center. In this time, 458 men have been rejected, 379 of whom have thus far been cleared at the Health Department Clinic. In 49, or 12.9 per cent, of those re-examined, the cause for rejection at the induction station was not confirmed, and the man was therefore considered suitable to be accepted in the Army.

A detailed cost analysis of personnel, equipment and materials necessary to complete this study indicated a total of \$23,614.20. Using this as a basis for computation, the unit cost to examine each man by roentgenogram was \$147 (the cost of taking a roentgenogram and its interpretation without any further follow up was \$13.91, 20, or 58.8 per cent of the total). The unit cost of rejecting a man for military service on the basis of the total cost was \$106.02 for inductees and \$122.37 for guardsmen.

Spillman has reported that the cost to the federal government of accepting a person with tuberculosis into the armed service is \$10,000. Thus, in these studies involving 41,819 inductees and 9541 guardsmen, or a total of 41,360 men, 561 persons with chronic pulmonary tuberculosis were rejected, representing an estimated saving to the government of \$5,610,000.—Reprinted from *Tuberculosis Abstracts*, October, 1941.

## NOTES

The following appointments to the teaching and research staff of the Harvard Medical School were recently announced by the University (effective this year): Norbert A. Wilhelm, M.D., St. Louis University School of Medicine, 25 lecturer on public health practice; William V. Knoll, M.D., College of Medical Evangelists, 35 Lucas N. Littauer Fellow in Pathology at the Collis P. Huntington Memorial Hospital, and Edward J. Welch, M.D., Harvard, 36, assistant medical adviser.

Dr. Leon K. Baldauf has been appointed to a full time professorship as head of the Department of Pathology at the School of Medicine at Middlesex University. He was formerly assistant in pathology at the Albany Medical College, resident pathologist at St. Louis City Hospital and professor of pathology and bacteriology at the University of Louisville School of Medicine, for the last three years, Dr. Baldauf has served as pathologist at the Cambridge City Hospital.

## CORRESPONDENCE

### PREMARITAL MEDICAL EXAMINATIONS

To the Editor: In reading the October 7 issue of the *Journal*, I came across Dr. Allen Johnson's remarks concerning premarital examinations on those persons who for several months or years have been traveling in the clouds of that grand passion and for the first time are about to put their feet once more on solid ground. What a rude awakening for the prospective groom to have a gloved finger roughly rammed through a spastic sphincter to massage a prostate in search of evidence of his past indiscretions.

Frankly, I believe there are a lot of us who are pretty much in the dark as to how far such an examination should be carried. Should it rest with a routine sample of blood or should smears also be taken? I think it would be of great help if there were some discussion of this in the *Journal*, and possibly a printed outline covering the essentials of such an examination in both men and women. Possibly some short form of examination sheet could be devised that could be incorporated with the regular history form, this would give uniform charac-

teristics throughout the State instead of a hit-or-miss sort of affair. Furthermore, if a patient could be shown such a blank and told this is the regular form sponsored and approved by the Massachusetts Medical Society and used by every physician in the State, I do not believe there would be much antagonism to taking of general smears. The man or woman would merely think, 'All the others have to go through the same procedure, so why should I complain?' I think this would greatly lessen the embarrassment of both parties, give a truer picture of the possibility of genitoinfectious disease and tide the doctor through the necessary procedures. I believe that such a slip of paper would well prove its worth to all concerned.

## BOOK REVIEWS

*Shock: Blood studies as a guide to therapy*. By John Scudder, M.D., Med.Sc.D. 4°, cloth, 323 pp with 55 illustrations and 5 plates, 3 in color. Philadelphia: J. B. Lippincott Company, 1940. \$5.50.

This volume reviews the whole subject of shock and advances as the author's special contribution the theory that the increase in the potassium content of the plasma observed in shock (as in most cases of tissue injury) is in fact an evidence of potassium poisoning that plays a part in causing the shock syndrome, and the recommendation of adrenocortical hormone (Eschmann) as an important chemotherapeutic measure—based on the belief that it tends to restore blood volume and relieve hemoconcentration, to raise blood pressure, to combat decrease in alkali reserve by aiding the retention of bases and to promote excretion of potassium and ammonia by the kidney, and that it accomplishes a number of other desirable things. The reader must decide for himself to what degree these beliefs are substantiated. Concerning potassium, it is clear that the diminution of effective blood volume, which is admittedly an underlying cause of the shock syndrome, precedes the hyperkalemia; there appears to be no evidence of an adrenocortical insufficiency in shock, although the use of the extract by the author in connection with other standard measures seems to have had good results.

Section I gives a historical introduction in three pages, Section II, on the theories of shock, is an enumeration of authorities supporting or opposing the responsibility of toxemia, the loss of circulating fluid, neurogenic dysfunction and adrenal exhaustion. Section III discusses blood changes in shock, Section IV, in discussing potassium, gives elaborate tables of lethal doses and seven pages of electrocardiograms in the experimental animal, Section V is entitled 'The Historical Treatment of Shock'—meaning presumably the history of the treatment of shock. The next four sections deal briefly with physical measures of hemoconcentration, experimental shock, normal and abnormal blood values in the human subject and limiting factors in potassium analysis. Section X, although entitled 'Advances in the Treatment of Shock' treats solely the use of the adrenocortical hormone, which is disposed of in five paragraphs, notwithstanding its importance as the author's main theme.

Sections XI and XII give adequate protocols of a number of cases illustrating various types of shock. The reader notes with interest the treatment followed which in most cases includes the standard and the newer methods, and he may or may not agree with the author's enthusiasm for the use of the adrenocortical hormone. Section XIV,

entitled "Historical Development in the Conception and Treatment of Shock," lists two hundred and twenty-nine names and endeavors, in a brief sentence or two, to indicate the part played by each: for example, "Cannon, 1923, against adrenal glands in shock." Sections XV and XVI attempt to cover, respectively, in the same way, "The Physiologic and Toxicologic Effects of Potassium" and "Some of the Functions of the Adrenal Glands." Section XVII, which is a bibliography of five hundred and thirty-three references, is followed by author and subject indexes and a useful ten-page laboratory manual.

The volume is a sumptuous one characterized by lavishness in paper, illustrations, charts and symbolic graphs. Many pages contain but a short paragraph or a small chart. There are thirty blank pages for personal notes by the reader. Three beautiful full-page colored illustrations of test tubes, flasks and the normal adrenal gland add nothing that could not be satisfactorily dealt with by a few lines of text. In general, the author presents a wealth of brief citation without the all-essential critical evaluation and integration that would add so much to its value.

In clinical problems, the success of treatment is often proportional to the exactitude of available data in diagnosis. Dr. Scudder does well to remind the reader that the pulse rate and quality, the blood pressures, the blood count and the hemoglobin estimation are occasionally misleading and that the hematocrit, the specific gravity of blood and plasma and the level of plasma proteins add important evidence of hemoconcentration and diminished effective blood volume, which may permit suspicion of impending shock before other evidence exists. In spite of his assurances of the simplicity and ease of these determinations, one cannot help believing that they may add difficulty, delay and even confusion in a situation demanding prompt action. The reviewer believes that in most cases the experienced surgeon who first shrewdly evaluates the facts and circumstances of the trauma and then considers the patient as a whole will rarely have difficulty in diagnosing impending or existing shock, and will meet all indications for treatment if he adopts the almost universally accepted simple methods, including the creation and maintenance of an effective blood volume by the introduction of blood, plasma or, sometimes, other fluids that will remain in the vascular channels.

*The Successful Error: A critical study of Freudian psychoanalysis.* By Rudolf Allers, M.D., Ph.D. 8°, cloth, 266 pp. New York: Sheed and Ward, Incorporated, 1940. \$3.00.

This is a useful book for those who wish to formulate their negative and critical reactions to psychoanalysis, and to those who have these feelings and wish to find them well expressed. Psychoanalysis is most actively promulgated by those who believe in it and those to whom it is a religion. They zealously defend it, but just as psychoanalysis has its adherents, it also has its critics, and Dr. Allers is one of these. The psychoanalyst will say that Dr. Allers does not understand psychoanalysis and that he is biased, hence not qualified to criticize it. In reading the book, one gets the impression that he has tried consciously to be objective, and certainly his criticism is based on his own philosophic and scientific training, which appears to be dignified. Dr. Allers has a medical background and training, and is probably better versed in the use of logic than most psychoanalysts. For these reasons and because his book is a thoughtful and sincere document, it is worth reading. Whatever the future may bring to prove the "rightness" or "wrongness" of psycho-

analysis, this book will stand as one of the systematic and logical objections to numerous excessive claims for the therapeutic system with which Dr. Allers deals in detail.

One of the best chapters is on the subject of psychoanalysis and medicine. It is too complicated to summarize, but any physician, whether he is a psychoanalyst or not, will find that chapter interesting. If the reader is a psychoanalyst, he will probably find it very irritating.

This is not just another aimless dig or jab at psychoanalysis. It is a carefully leveled, well-aimed thrust.

*Medical Progress: Annual, 1940.* A series of fifty-two reports published during 1940 in the *New England Journal of Medicine*. Managing Editor: Robert N. Nye, M.D. 8°, cloth, 625 pp. Springfield, Illinois: Charles C Thomas, 1941. \$4.00.

Each week in the *New England Journal of Medicine*, there appears a critical review of a definite subject by a man well qualified to evaluate the current progress in the field. These reviews are usually more than a mere report on the current literature, for they discuss the problems in general, particularly in relation to recent advances. The fifty-two articles published in 1940 have now been collected into a volume of great value to medical students, practitioners and specialists alike. The quality of the articles is extremely high, and the reviewer knows of no other annual publication that sets a finer standard. The papers are clearly written, and although they are scientifically accurate and often detailed in their exposition of the subject, the material is presented in such a way that the ordinary practitioner may read it with understanding. The articles contain bibliographies. The book should receive the widest recognition, and it is difficult to conceive of any doctor in the practice of medicine who would not improve his practice by reading part or all of this volume. For the specialist, moreover, who desires to keep up in fields other than his own, this book offers an invaluable opportunity. In addition, the book should be compulsory reading for all third-year and fourth-year medical students.

*Necropsy: A guide for students of anatomic pathology.* By Béla Halpert, M.D. 12°, cloth, 75 pp. St. Louis: The C. V. Mosby Company, 1941. \$1.50.

This small book describes the autopsy technic practiced by Ghon and adopted by the author. The descriptions of technic are not always adequate because of the lack of illustrations. Its principal value lies in the suggestions of possible pathological findings in the various systems of the body.

## NOTICES

### MASSACHUSETTS MEDICAL BENEVOLENT SOCIETY

The annual meeting of the Massachusetts Medical Benevolent Society will be held at the Boston Medical Library on Monday, October 27, at 5:15 p.m. A meeting of the council will be held at 5 p.m.

### MASSACHUSETTS MEMORIAL HOSPITALS

The regular staff meetings of the Massachusetts Memorial Hospitals will be held in the Evans Memorial Auditorium at 8:15 p.m. on October 31, January 2, February 27 and April 24. Dr. Chester S. Keefer will be the chairman. At the first meeting, Dr. Joseph F. Ross will speak on "The Metabolism of Radioactive Iron."

## MASSACHUSETTS GENERAL HOSPITAL

The clinical staff meetings of the Children's Medical Service of the Massachusetts General Hospital were resumed on Friday, October 17, in the Ether Dome at 12 m. Subsequent meetings will be held on the following Fridays: October 31, November 14 and 28, December 12, and January 2, 16, and 30

## ROBERT BRECK BRIGHAM HOSPITAL

Dr. Carl C. Seltzer will speak on "Anthropometry and Arthritis: Difference between rheumatoid and degenerative joint diseases, males and females" at the Robert Breck Brigham Hospital on Monday, October 27, at 8 p.m. Drs. E. A. Hooten and Walter Bauer will lead the discussion.

Physicians and medical students are cordially invited

## PORTSMOUTH NAVAL HOSPITAL

There will be a meeting of the staff of the United States Naval Hospital, Portsmouth, New Hampshire, on Tuesday, November 4, at 8 p.m. Dr. Merrill Moore, of Boston, will speak on "Alcoholism: Its cause and treatment."

The members of the local societies in and about Portsmouth are cordially invited to attend

## SOCIETY MEETINGS AND CONFERENCES

## CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, OCTOBER 26

## MONDAY, OCTOBER 27

- 11:15-1:15 p.m. Clinicopathological conference Peter Bent Brigham Hospital amphitheater
- 5:00 p.m. Massachusetts Medical Benevolent Society Boston Medical Library, 8 Fenway
- 8 p.m. Anthropometry and Arthritis: Difference between rheumatoid and degenerative joint diseases, males and females Dr. Carl C. Seltzer Robert Breck Brigham Hospital

## TUESDAY, OCTOBER 28

- 9:00-10:00 a.m. Medical clinic Dr. S. J. Thannhauser Joseph H. Pratt Diagnostic Hospital
- 11:15-1:15 p.m. Clinicopathological conference Peter Bent Brigham Hospital amphitheater
- 5:00 p.m. The Chemical Reactions of the Body Fats Prepared by Dr. Rudolf Schoenheimer and delivered by Professor Hans T. Clarke Edward A. Dunham Lecture Harvard Medical School amphitheater, Building C
- 8:00 p.m. Massachusetts Society of X-Ray Technicians Inc. New England Baptist Hospital

## WEDNESDAY, OCTOBER 29

- New England Postgraduate Assembly Sanders Theatre Harvard University, Cambridge
- 9:00-10:00 a.m. X-ray Demonstration Or Alice Einstein Joseph H. Pratt Diagnostic Hospital
- 12:00 m. Clinicopathological conference Children's Hospital
- 5:00 p.m. The Chemical Reactions of the Body Proteins Prepared by Dr. Rudolf Schoenheimer and delivered by Professor Hans T. Clarke Edward A. Dunham Lecture Harvard Medical School amphitheater, Building C
- 7:00 p.m. Neisserian Medical Society of Massachusetts Hotel Kenmore, Boston

## THURSDAY, OCTOBER 30

- New England Postgraduate Assembly Sanders Theatre Harvard University, Cambridge
- 8:30 a.m. Combined clinic of the medical, surgical, orthopedic and pediatric services of the Children's Hospital and the Peter Bent Brigham Hospital at the Children's Hospital Conducted by Dr. F. R. Ober
- 9:00-10:00 a.m. Medical clinic Or S. J. Thannhauser Joseph H. Pratt Diagnostic Hospital
- 3:00-6:00 and 7:00 p.m. Massachusetts Public Health Association Commander Hotel Cambridge
- 5:00 p.m. The Dynamic State of the Body Constituents Prepared by Dr. Rudolf Schoenheimer and delivered by Professor Hans T. Clarke Edward A. Dunham Lecture Harvard Medical School amphitheater, Building C

8:00 p.m. Some Local Uses of Estrogenic Hormones in Obstetrics and Gynecology Dr. Norris W. Vaux Journal Club meeting, Boston Lying in Hospital

## FRIDAY, OCTOBER 31

- 9:00-10:00 a.m. The Differential Diagnosis of Hemoglobinuria Dr. T. Hale Ham Joseph H. Pratt Diagnostic Hospital
- 12 m. Clinical staff meeting of the Children's Medical Service Massachusetts General Hospital Ether Dome
- 8:15 p.m. The Metabolism of Radioactive Iron Joseph F. Ross Massachusetts Memorial Hospital

## SATURDAY, NOVEMBER 1

- 9:00-10:00 a.m. Presentation with discussion dispensary and district cases Joseph H. Pratt Diagnostic Hospital
- \*Open to the medical profession

## BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

*Trauma and Disease.* Edited by Leopold Brahdy, M.D., physician in charge of occupational diseases and injuries in the Office of the Corporation Counsel of the City of New York, and lecturer in radiology, New York University Medical School; and Samuel Kahn, M.D., medical examiner in the Bureau of Workmen's Compensation of the Department of Labor, State of New York. Second edition. 8°, cloth, 655 pp., with 13 illustrations and 13 tables. Philadelphia: Lea and Febiger, 1941. \$7.50.

*The Furtherance of Medical Research.* By Alan Gregg, M.D., director for the medical sciences, Rockefeller Institute. 8°, cloth, 129 pp. New Haven: Yale University Press, 1941. \$2.00.

*Leaders of Medicine: Biographical sketches of outstanding American and European physicians.* By Solomon R. Kagan, M.D. 8°, cloth, 176 pp., with 4 illustrations. Boston: The Medico-Historical Press, 1941. \$3.00.

*The Foot and Ankle: Their injuries, diseases, deformities, and disabilities, with special application to military practice.* By Philip Lewin, M.D., associate professor of bone and joint surgery, Northwestern University Medical School professor of orthopedic surgery, Post-Graduate Medical School of Cook County Hospital, attending orthopedic surgeon, Cook County Hospital, attending orthopedic surgeon, Michael Reese Hospital, Chicago, and consulting orthopedic surgeon, Municipal Contagious Disease Hospital, Chicago. Second edition. 8°, cloth, 665 pp. with 304 illustrations. Philadelphia: Lea and Febiger, 1941. \$9.00.

*Nostradamus: The man who saw through time.* By L. McCann. 8°, cloth, 421 pp. New York: Creative Art Press, Incorporated, 1941. \$2.75.

*The New International Clinics: Original contributions, clinics, and evaluated reviews of current advances in medical arts.* Edited by George Morris Piersol, M.D., professor of medicine, Graduate School of Medicine, University of Pennsylvania, Philadelphia. Vol. III, N. S. 4, 15 8°, cloth, 300 pp. Philadelphia: J. B. Lippincott Company, 1941. \$3.00.

*The Roentgen Density of the Cystine Calculus: A roentgenographic and experimental study, including a comparison with more common uroliths.* By Axel Renan. Translated from the Swedish by Catherine Djurklou. paper, 148 pp., with 67 illustrations and 23 tables. Stockholm: P. A. Norstedt and Sons, 1941. 15 Sw. Cr.

*Essentials of General Surgery.* By Wallace P. Ritt, M.D., clinical assistant professor, Department of Surgery, University of Minnesota Medical School. 8°, cloth, pp., with 237 illustrations. St. Louis: The C. V. Mosby Company, 1941. \$8.50.

*Bibliographia primatologica: A classified bibliography of primates other than man.* Part I: Anatomy, embryology and quantitative morphology; physiology, pharmacology and psychobiology; primate phylogeny and miscellanea. By Theodore C. Ruch, B.Sc., Ph.D., Yale University School of Medicine. With an introduction by John F. Flannery, B.S., A.M., Ph.D., Yale University School of Medicine. 4°, cloth, 241 pp. Springfield, Illinois: Charles C. Thomas, 1941. \$8.50.

*Sulfanilamide and Related Compounds in General Practice.* By Wesley W. Spink, M.D., associate professor of medicine, University of Minnesota Medical School. cloth, 256 pp. Chicago: The Year Book Publisher, Incorporated, 1941. \$3.00.

*Society and Medical Progress.* By Bernhard J. Stern. cloth, 264 pp. Princeton: Princeton University Press, 1941. \$3.00.

*A Manual of Bandaging, Strapping and Splinting.* Augustus Thorndike, Jr., M.D., associate in surgery, Harvard Medical School, and surgeon to the Department of Hygiene, Harvard University. 16°, paper, 144 pp., 117 illustrations. Philadelphia: Lea and Febiger, 1941. \$1.50.

*Beiträge zur Röntgendiagnostik: Der Otitis Media und ihrer Komplikationen im Schlafenden.* By

## LIVER DOSAGE IN PERNICIOUS ANEMIA\*

### Failure of Quantitative Storage of Hematopoietic Principle

WILLIAM B. SEYMOUR, MD,† ROBERT W. HEINLE, MD,† AND  
FRANKLIN R. MILLER, MD,‡

CLEVELAND

**T**REATMENT of patients with pernicious anemia by parenteral liver extract has become such a well established procedure that it needs no further discussion. The usual method involves the administration of conveniently sized doses of liver extract at regular intervals of one, two, three and, occasionally, four weeks. The size of each dose and the interval between treatments must be regulated by the requirements of the patient as determined by observation in each case.

Normal persons manufacture the hematopoietic principle effective in pernicious anemia by the interaction of intrinsic (gastric) factor and extrinsic (food) factor.<sup>1</sup> This reaction presumably takes place in the intestinal tract,<sup>2</sup> and the product of the interaction is recovered from the liver in the preparation of the liver extracts effective in the treatment of pernicious anemia. It has been thought that the liver might be a storehouse for the hematopoietic principle,<sup>3-6</sup> and that its only function is to release this principle as the necessity arises. If it were possible for the liver to store the hematopoietic principle quantitatively without any excretion or destruction, it is conceivable that large amounts of liver extract might be administered over a short period to patients with pernicious anemia and thus enable them to remain in remission as long as if the same total dose of liver extract were given in the usual manner of smaller doses at regular, frequent intervals. Miller,<sup>7</sup> in 1936, suggested this possibility and presented data showing that some such storage might take place. Strauss and Pohle<sup>8</sup> sub-

sequently presented similar data indicating that, although some storage may take place, patients with pernicious anemia generally do not remain in remission so long when treated with single massive doses as when they receive the same total dose in smaller amounts at spaced intervals.

The observations reported here were made on 9 patients with pernicious anemia in remission and 13 patients with pernicious anemia in relapse. Six were men, and 16 were women. All had been observed at some previous time during both relapse and remission. The 9 patients in remission had been followed previously for ten to forty-six weeks during remission; during this time they received doses of liver extract at intervals of two or three weeks, and the individual requirement was ascertained. The 13 patients in relapse had also been followed from ten to forty-six weeks during a remission, so that their individual maintenance dosage of liver extract was similarly established. Subsequently, these 13 patients failed to keep scheduled appointments for treatment, so that when next seen they were in relapse, at which time the observations reported here were begun.

For purposes of discussion, patients were arbitrarily considered to be in remission when the red cell count was 4,000,000 or more, with a hemoglobin of 90 per cent (14.0 gm per 100 cc.). Values less than these constituted a relapse. All patients had typical Addisonian pernicious anemia, including the usual blood findings, absence of free hydrochloric acid after subcutaneous administration of histamine and varying degrees of posterolateral column sclerosis. All had been seen in relapse at least once before the beginning of this study, and all had responded to liver extract or oral stomach preparations in the expected manner.

Figure 1 shows the results when the 9 patients

\*From the H. K. Cushing Laboratory of Experimental Medicine, Department of Medicine, Western Reserve University, and the Medical Service, Lakeside Hospital.

†Instructor in Medicine, Western Reserve University physician, University Hospitals of Cleveland.

‡Formerly assistant professor of medicine, Western Reserve University physician, University Hospitals of Cleveland.

in remission were treated with massive doses of liver extract. These patients received 55 to 140 U.S.P. units of parenteral liver extract<sup>9</sup> in ten to thirty days' time, after which no liver or liver extract was given until the blood showed evidence

FIGURE 1. Patients with Pernicious Anemia in Remission.

The actual durations of remission (cross-hatched areas) following massive doses of liver extract are compared with the calculated durations of remission (solid areas) that would have obtained if the same amount of liver extract had been given in the usual intermittent doses.

of relapse as previously defined. In Figure 1, the cross-hatched bars represent the actual length of time the patients remained in remission following the massive liver treatment; the solid bars represent the calculated length of time the patients would have remained in remission had the same total dose of liver extract been administered in smaller amounts spaced at regular intervals of two or three weeks. In all but 3 of the 9 cases, relapses occurred much sooner with massive-dose therapy than they would have occurred with the intermittent-dose method. In Cases 3, 5 and 6, the interval of remission was about the same. The explanation of why these 3 cases were apparently able to store the liver extract quantitatively will be considered subsequently.

It must be mentioned, at this point, that there may have been some error in determining the actual maintenance dose of liver extract required by these patients when they were treated in remission with the usual small, intermittent doses. An effort was made to give the patients just enough liver extract to cause them to remain in remission. However, it is probable that a somewhat greater amount was given than was actually required, since none of the patients were allowed to relapse during the period of maintenance observation. Even though this factor caused the results of massive dose treatment to appear more favorable, they are generally not so good as those

which would have been obtained had the same total dose of liver extract been given in small, regular, intermittent doses. Table 1 shows the volume and number of units of liver extract utilized per week in both the massive-dose and intermittent-dose methods of treatment.

It can also be seen from Table 1, by comparing doses in cubic centimeters with the units contained, that both crude and concentrated liver

9	0.19	2.88	2.10	2.10

extracts were employed in the study of these patients. We do not wish to discuss the relative merits of these two types at this time and only call attention to the fact that, so far as maintenance of blood levels is concerned, one type was as effective as the other.

The results when massive doses of liver extract were given to patients in relapse are shown in Table 2. In these cases, the duration of the actual

†100 per cent hemoglobin = 15.6 gm. per 100 cc.

remission cannot be compared with that which would have resulted if treatment had been instituted during remission, since there is no method of calculating how much liver extract these patients utilized before remission was attained. These 13 patients were given 90 to 380 units of liver ex-

tract intramuscularly in ten to thirty days. A maximal reticulocyte response and a rapid increase in red blood cells and hemoglobin occurred in each case. It is evident that these patients were able to attain and maintain remission for longer periods than if liver extract had been given in dosage sufficient only to produce a maximal reticulocyte response. All these patients attained remission blood levels and remained in remission for thirteen to twenty-nine weeks without further treatment of any sort.

As previously noted from Figure 1 and Table 2, there is considerable variation in a patient's ability to store liver extract. The most reasonable explanation of this depends on the fact that pernicious anemia is the result of a relative and not necessarily an absolute deficiency of gastric intrinsic factor. Goldhamer<sup>10</sup> has shown that patients with pernicious anemia have some intrinsic factor in their stomachs, although it is obviously not present in sufficient quantities to prevent the occurrence of anemia. If gastric juice is removed daily from certain of these patients, pooled until large quantities are obtained, and administered to the same or other patients with pernicious anemia in relapse, a hematopoietic response ensues, similar to that produced with normal gastric juice and indicating that some intrinsic factor is present.

It is reasonable to assume, therefore, that there are all degrees of pernicious anemia from mild to severe, depending on the degree of deficiency of intrinsic factor. The patients with mild cases, although they do not manufacture enough hematopoietic principle to prevent anemia, obviously manufacture more hematopoietic principle than those with severe cases and, hence, greater deficiencies, and the former need less liver extract than the latter.

To test this hypothesis, we selected 2 patients who had mild pernicious anemia as evidenced by

eral months by the daily feeding of whole liver. At the beginning of the observation period shown in Table 3, all liver and stomach products were removed from the diet, and 120 gm. of beef or two eggs daily were added—both beef and eggs are known to be good sources of extrinsic factor.<sup>11</sup> On this regimen, the patient remained in remission for a period of thirty-nine weeks, although no specific therapy was administered. At the end of this period, she was unwilling to follow the diet longer, and therapy with liver was resumed.

The second patient, C. R., in addition to pernicious anemia, had hypertension and angina pectoris. Twenty-eight weeks preceding the observation period recorded in Table 4, the patient re-

\*The diet included 120 gm of beef or two eggs daily. No liver or liver extract was administered during this period. Prior to this period the patient had maintained herself on whole liver by mouth.

the fact that they did not require so much liver or liver extract to maintain remission as the average case of pernicious anemia did. The first patient, H. P., had been kept in remission for sev-

ceived a single dose of 10 units (2 cc.) of liver extract intramuscularly. At the beginning of the period recorded, 60 to 120 gm. of beef or one to two eggs daily were added to the diet. The patient disliked both these foods and had not been eating either regularly. She remained in remission for fifty weeks, at the end of which she refused to include the items in her diet, and the blood showed a relapse. At this time, she was given 45 gm. of brewer's yeast daily. This material, which has a high protein content, is also an excellent source of extrinsic factor.<sup>12</sup> The blood showed improvement, but after six more weeks the patient

refused to ingest the yeast; another relapse occurred. She was given 5 units (1 cc.) of liver extract intramuscularly, with good results. At that time, she again started to eat beef or eggs, but because of her dislike for these foods, frequently omitted them from her diet. In spite of this, she received a total of only 52 units of liver extract intramuscularly during another forty-eight weeks. The patient decided that treatment should not be given so long as the red-cell count was over 4,000,000; this explains why the hemoglobin values were allowed to fall below 90 per cent (14.0 gm. per 100 cc.) on several occasions. When last seen, the patient felt perfectly well, showed no signs of progression of the posterolateral-column sclerosis, and had no complaints except frequent, mild attacks of angina pectoris.

There can be no doubt that these 2 patients represent true cases of pernicious anemia. Both were observed in severe relapse, and both reacted to liver with the usual reticulocyte response and increase in red-cell count and hemoglobin. Free gastric hydrochloric acid was absent in both after histamine was administered. The first patient had a moderate amount of posterolateral-column sclerosis. During subsequent periods of observation, it was found that even when these patients were given diets containing what is considered to be a normal amount of protein, an occasional dose of liver or liver extract was needed to maintain normal red-cell counts and hemoglobin levels. This is demonstrated in the last period of Table 4, but is not illustrated by the course of the first patient (Table 3), who has not been followed so regularly since the completion of the period shown.

It might reasonably be assumed that these two patients went into spontaneous remission coincident with the institution of the diet containing larger amounts of extrinsic factor, since it is well known that patients with pernicious anemia can undergo spontaneous remission lasting for months or even years. Although the explanation of such remissions has not been understood, it seems likely that either a spontaneous increase in gastric intrinsic factor or an increase of extrinsic factor in the diet might account for them. In the two cases described above, we believe that spontaneous remission occurred as a result of increasing extrinsic factor in the diet. It is probable that certain cases of spontaneous remission observed in the past resulted when patients, for one reason or another, increased the amount of extrinsic factor in the diet.

## DISCUSSION

It is unnecessary to assume any actual storage of hematopoietic principle to account for the fact that patients with pernicious anemia treated with massive doses of liver extract remain in remission for varying long periods. Regardless of the degree of deficiency of the gastric intrinsic factor, any patient can attain and maintain remission for some time after liver extract is given. The time that remission is maintained is longer in the patients with mild cases, who produce moderate amounts of hematopoietic principle, than it is in those with severe cases, who produce less hematopoietic principle.

The 2 cases maintained on extrinsic factor for long periods were sufficiently mild that only a small amount of extraneous hematopoietic principle was necessary to augment that made by the patients themselves. The fact that addition of extrinsic factor improves the formation of hematopoietic principle has been interpreted to be the result of a mass-action chemical phenomenon.<sup>12</sup> Since intrinsic factor added to extrinsic factor equals hematopoietic principle, increasing extrinsic factor causes an increase in the formation of hematopoietic principle, even though the intrinsic factor is present in less than normal amount.

Thus, the variation in amount of liver extract required by different patients is adequately explained. If the deficiency of intrinsic factor is relatively small and the amount of extrinsic factor in the diet is relatively large, less liver extract is necessary than if the reverse is true.

## SUMMARY AND CONCLUSIONS

Patients with pernicious anemia in remission given large doses of liver extract within a brief period remain in remission for varying periods. This time is generally not so long as that when the same total dose of liver extract is administered in small, intermittent doses.

Patients with pernicious anemia in relapse given large doses of liver extract in a short period attain and maintain remission for varying lengths of time without further treatment.

If hematopoietic factor is stored in the body, such storage is not quantitative when large doses of liver extract are administered in a short period. The fate of the unused hematopoietic principle is unknown.

By augmenting the extrinsic factor in the diet, two patients with mild pernicious anemia were maintained in remission for long periods without any specific treatment.

The degree of deficiency of intrinsic factor and the amount of extrinsic factor in the diet of patients with pernicious anemia probably account for the individual variation in requirements of liver extract.

## CONTROLLED ADMINISTRATION OF FLUID IN SURGERY\*

JOHN SCUDDER, M.D.,† AND EDWARD SELF, M.D.‡

NEW YORK CITY

ROBERT Boyle,<sup>1</sup> the physicist, was interested in the density of many things. In 1683, while weighing blood and serum, he noted that in acute disease the specific gravity was higher and in chronic disease lower than normal. In the next century, Jurin<sup>2</sup> confirmed these observations. However, it was not until the nineteenth century that this knowledge was applied clinically. O'Shaughnessy<sup>3</sup> in England and Wittstock<sup>4</sup> in Germany demonstrated in 1831 that in Asiatic cholera the specific gravity of blood is considerably higher than normal.

Roy,<sup>5</sup> using a simplified method of obtaining the density of blood, showed by animal experimentation in 1884 that the blood becomes heavier in shock. This phenomenon occurs before any fall in blood pressure. Roy wished to find where the fluid lost from the blood could be found. By carrying out density determinations on the intestinal wall and on other organs, he showed that, in shock, fluid shifts from the blood into these tissues.

The first practical application of Roy's work was in India. Rogers,<sup>6</sup> the Surgeon General of India, considered the mortality in Asiatic cholera to be too high. In this disease, the patient goes into typical dehydration collapse due to vomiting, sweating and copious rice-water stools. A cold clammy skin, weak thready pulse, great mus-

cular weakness and marked prostration supervene. The only pulsating vessels are often the carotid arteries. The blood is viscid and thick, and the specific-gravity values of peripheral blood are often above 1.070. Besides hemoconcentration, there is a decrease in the sodium, an increase in the potassium concentration of the blood and a fall in the blood chloride and bicarbonate contents.

Both hypotonic and isotonic solutions had given disappointing results in cholera. Rogers introduced a slightly hypertonic (1.5 per cent) sodium chloride solution, and controlled the large administration of fluid by following the specific gravity of the peripheral blood. At times, as much as 10 to 12 liters was given within twenty-four hours before hemodilution was secured. Rogers issued an order that fluids should be stopped when the specific gravity of the blood reached 1.050. This was to prevent giving too much. This type of therapy reduced the mortality rate from Asiatic cholera at the Calcutta General Hospital from 59 per cent during the decade 1895-1905 to 26 per cent during the years 1910-1914.

The similarity between Asiatic cholera, intestinal obstruction and traumatic shock has often been noted. The chemical changes in the blood are identical.<sup>7</sup>

During World War I, Cannon<sup>8</sup> reported hemoconcentration in soldiers suffering from wound shock. Erythrocyte counts of 6,000,000 to 8,000,000 were associated with high mortality, especially if there was a great disproportion between the counts taken on capillary and those taken on venous blood. For some reason, this very im-

§Surgical resident, Presbyterian Hospital.

portant observation is not widely known. Today, specific-gravity determinations are supplanting erythrocyte counts because of their far greater accuracy and sensitivity.<sup>9-11</sup>

The second test that is of value in assaying the degree of dehydration is the hematocrit or cell volume. During the early part of the nineteenth century, it was appreciated that in cholera the blood lost water. O'Shaughnessy<sup>3</sup> applied the term "crassamentum" to the solid matter that settled out on standing. In some cholera cases, the

can be determined within fifteen minutes, and afford accurate information about the state of the peripheral and venous circulating systems. They furnish data concerning the state of hydration. In cases of injury, changes of the specific gravity of capillary blood herald the approach of shock. One is thus forewarned and can institute therapy at a time when such corrective measures are most effective. These tests can differentiate shock due to internal blood loss from typical dehydration or traumatic shock before changes in blood pressure

water loss from the blood was so extreme as to leave only 27.5 per cent fluid and 72.5 per cent solids. This may be taken as the first objective measurement of decreased plasma volume in shock.

Blix<sup>12</sup> presented at Upsala the first *Haematokrit*. It was modeled after the *Laktokrit* used in the dairy industry. With this apparatus, Hedin<sup>13</sup> in 1891 reported values for normal men and women. In dehydration, whatever the cause, an increase in the hematocrit is characteristic.

The third test weighs a drop of plasma. This gives the total plasma solids and serves as another measure of dehydration.

The importance of the plasma proteins is now well recognized. One of their functions is protective. They also serve as a measure of dehydration. On account of the work of Weech and his associates,<sup>14</sup> one is able to compute the total plasma proteins from the specific gravity of the plasma. This is readily accomplished by using the modified Barbour and Hamilton apparatus<sup>7</sup> for the measurement of the specific gravities of body fluids.

These four values—the specific gravity of the peripheral blood, the hematocrit, the specific gravity of the plasma and the total protein content—

and before the appearance of the classic symptoms of shock.

In the postoperative care of the patient, the data furnished by these tests indicate whether blood should be administered; whether plasma and proteins should be used; whether salt solution is indicated; and, above all, when fluid therapy should be stopped. In addition to these helpful points, one can ascertain whether the fluid given is being utilized. In treating impending shock, should the blood become more concentrated after the administration of saline, one is immediately warned of the approach of a grave crisis. It is in just this state that the use of a potent adrenocortical hormone, along with salt, causes a reduction of hemoconcentration and a decrease in blood viscosity.

The restoration of blood volume in shock is essential. The restoration of blood volume with the proper type of fluid is even more important. In cases with renal failure or anuria, the flooding of the vascular system with intracellular water is poor therapy. For normal function, the differential salt concentration between the intracellular and extracellular compartments is necessary. Factors that upset this balance are harmful, in particular hypertonic solutions given in the dehydrated

state. Kidney function must be restored early in injury. The accumulation of intracellular salts in the blood plasma, due both to damage and to failure of excretion, tends to change the normal

state and was equivalent to 1500 cc. of liquid) was started intravenously, and the patient taken to the operating room for débridement and fixation of the fracture.

The cell volume and specific gravity of the peripheral blood were within normal limits (Table 1 and Fig. 1).

FIGURE 1. Traumatic Shock Due to an Automobile Accident: Multiple injuries, with compound fracture of the tibia.

ratio between intracellular potassium and extracellular sodium ions.

The following case of traumatic shock illustrates some of these points.

#### CASE REPORT

S. G. (P. H. 638287), a 59-year-old man, was brought to the hospital by ambulance a few minutes after an automobile accident in which he had sustained multiple contusions, lacerations and a compound fracture of the tibia. The patient was in primary shock, with a blood pressure of 80/60 and a pulse of 60. The leg had been fixed in a Thomas splint. The patient was conscious and oriented, but could not recall details of the accident.

He was given  $\frac{1}{4}$  gr. of morphine after blood had been secured for chemical studies and groupings. An infusion of serum (which had been reconstituted from the dried

The specific gravity of the plasma and the plasma proteins were elevated, findings that suggested a case of secondary anemia exhibiting hemoconcentration. The values of the sodium, potassium and chloride concentrations were not available at this time and illustrate that these determinations are valueless in directing emergency therapy on account of their time-consuming nature. They afford, however, valuable information about the effects of therapy when one reconsiders a case.

Blood dilution was secured with the serum, as shown by the falls in the hematocrit, specific gravity of capillary blood and plasma proteins. Eventually, there were decreases in the chloride and sodium concentrations, but the greatest change was a marked increase in the potassium concentration (from 3.6 to 5.3 milliequiv. per liter)<sup>15</sup> within 18 hours after the accident. Physiologic saline and Eschatin (adrenocortical extract) were withheld in the initial treatment because we wished to ascertain the effect

of serum alone on both the clinical and chemical aspects of shock.

On the following day, the patient went into typical secondary shock, which was combated with oxygen, infusions of physiologic saline and blood transfusion.

*Comment.* The administration of adrenocortical extract and salt during the initial treatment might have prevented the changes in sodium, potassium and chloride concentrations. The 58 per cent decrease in cell volume may have indicated overdilution of the blood, and points to the recommendation of giving 500 cc. of blood with every 500 cc. of plasma or serum, as recently advocated by Kekwick and his co-workers.<sup>16</sup>

### SUMMARY AND CONCLUSIONS

Four simple tests based on elementary physical chemistry are presented as a means of judging the state of hydration in the capillary and venous circulating systems. Their value lies in their simplicity, reproducibility and ease of mastery. Their practicability lies in the minimum amount of equipment necessary.

These tests are useful in shock, since they forewarn of its approach and hence allow early therapy. One case of shock is presented in which 1500 cc. of serum was used. The overdilution of the blood and the change in the electrolyte pat-

tern indicate that blood should have been given along with the serum and suggest that the administration of sodium and adrenocortical extract might have lessened the electrolyte changes.

## PRIMARY CARCINOMA OF THE URETHRA IN THE MALE\*

### Report of a Case

MILTON O. ZUCKER, M.D.,† AND GEORGE J. WEINSTEIN, M.D.‡

NEW YORK CITY

PRIMARY carcinoma of the urethra in the male is a comparatively rare disease. The first authentic case was reported in 1861 by Hutchinson.<sup>1</sup> In October, 1939, Kreutzmann and Coloff<sup>2</sup> searched the entire medical literature, and abstracted almost all the original case reports. With the addition of their own 2 cases, they brought the total of reported cases to 150. We report the following case because it serves well to illustrate the usual clinical course that this disease follows, the etiologic factors most commonly implicated and the diagnostic pitfalls most frequently encountered.

### CASE REPORT

A. L., a 58-year-old man, was admitted to the Lincoln Hospital on December 31, 1938. The patient had had some preliminary examination and treatment in another institution for the 2½ months directly preceding admission. Thirty-five years before hospitalization, he had had gonorrheal urethritis. He had no symptoms referable to the genitourinary tract until 5 years prior to entry, when he developed difficulty in starting the urinary stream,

some dribbling and occasionally a drop or two of bleeding at the end of micturition. This, associated with severe burning and urgency, made him seek treatment. He was seen at two hospital outpatient clinics, and was told that he had a urethral stricture. He was treated by numerous and repeated dilatations, and appeared to be peculiarly unresponsive to therapy. Each treatment was followed by severe pain and bleeding. The stricture did not seem dilatable. The patient was admitted to the wards of one of these first hospitals because of the fact that he had developed a markedly stammering urinary stream, frequency, nocturia and a urethral discharge. He had 200 cc. of turbid residual urine. X-ray studies of the kidneys, ureter and bladder showed no abnormalities. Cystoscopic examination revealed what appeared to be numerous strictures along the posterior urethra, moderate prostatic enlargement and generalized cystitis. It was believed that the patient's symptoms were largely due to the prostatic hypertrophy, and that they could be alleviated by prostatectomy. Hence, a bilateral vasectomy and suprapubic cystotomy were performed, in preparation for enucleation of the prostate. Ten days later, there was a profuse urethral discharge and marked perineal induration. With the appearance of a fluctuant mass, an incision was made in the perineum, and 200 cc. of foul pus was obtained. The perineal induration increased and spread, requiring repeated incisions and drainage. About a week before the patient entered Lincoln Hospital, it

was found that sounds could not be passed into the bladder because of obstruction at the junction of the membranous and prostatic portions of the urethra. Nor could sounds be passed into the bladder through the perineal

Carcinoma of the urethra is a slowly progressive disease, affecting most frequently the membranous and bulbous portions of the urethra. Its

FIGURE 1. Typical *Acanthoma*, Showing Numerous Keratinizing Pearls

incisions. Fluid injected into the urethral meatus came through the perineal wounds.

On admission to Lincoln Hospital, the patient appeared acutely ill and cachectic. On January 26, 1939, after he had shown some improvement in his general condition, the perineum was completely exposed by enlarging the previous incisions. All necrotic tissue was removed, and the wound was irrigated and thoroughly packed. With increased drainage, the patient improved somewhat, but on February 14, because of extension of the infection in the perineum, the area was again incised. Suppuration involving the left ischiorectal fossa as high up as the left femoral triangle was found. There was marked sloughing of the bulbous and membranous urethra, with a urethroperineal fistula. The entire perineal area contained what seemed to be dense, cauliflowerlike inflammatory masses. Because of this appearance and the indolent healing, cancer was suspected, and a specimen removed for biopsy. Histologic examination of this tissue revealed that the mass was a typical squamous-cell epithelioma of the adult type (Fig 1), the commonest type of cancer of the urethra. X-ray examination of the pelvis, lumbar spine and long bones showed no evidence of metastases. There was no adenopathy.

The patient failed rapidly and expired about 1 month after this operation. Autopsy revealed that the membranous and bulbous portions of the urethra were entirely destroyed by a cauliflowerlike tumor (Fig 2), which extended throughout the entire length of these parts of the urethra.

recognition and course depend to some degree on the depth of the lesion in the urethra.

The initial symptoms of the disease are similar to and almost always mistaken for those of urethral stricture. However, suspicion should be aroused if presumable urethral strictures appear unresponsive to the usual treatment, or if perineal abscesses are intractable. Spread is by direct extension, with involvement of wide areas, which ultimately become necrotic and infected. Metastases are unusual, and regional adenopathy is most frequently due to infection. Distant metastasis is almost never seen, but when it does occur, the lung is the most frequent site.

The symptomatic course is divided into four stages by Kretschmer,<sup>3</sup> as follows: dysuria, retention and urethral discharge—the latter, if hemorrhagic, should lead one to suspect cancer; local tumor formation; periurethral infiltration with urine; and sinus formation. It is not until the latter two stages that carcinoma is suspected, so that diagnosis is generally late.

The etiology of urethral carcinoma, like that of all neoplastic disease, remains unknown. The

commonly held belief is that the condition is a metaplasia resulting from inflammatory irritation—in a large percentage of cases, gonorrheal urethritis is a common predecessor—or from re-

SUMMARY

A case of urethral carcinoma in the male is presented. The usual clinical course, the diagnostic pitfalls and the etiologic theories are illus-

peated trauma, such as that of repeated dilatations. Prognosis, which as a rule is very poor, can be improved only by early treatment. This necessitates early diagnosis. More frequent urethrocopies, with biopsy, in cases of intractable stricture, periurethral abscesses and sinuses that fail to heal, would increase the number of cases recognized. Treatment consists in either radical resection or deep x-ray therapy, or both.

trated and discussed. A plea is made for careful study, with biopsy, of intractable strictures, periurethral abscesses and sinuses that fail to heal, to facilitate early diagnosis and to improve the prognosis.

## MENINGOCOCCEMIA WITHOUT MENINGITIS\*

## Report of a Case

LESTER D. WATSON, MD†

MILTON, MASSACHUSETTS

**M**ENINGOCOCCEMIA, as a disease entity, without meningitis or other complications, has been known only in the last forty years, the first case having been described by Salomon<sup>1</sup> in 1902. Since then, the disease has been widely reported.

Carbonell and Campbell<sup>2</sup> have defined and described the disease clearly and completely in their report of 3 cases, which, however, were treated with serum just at the dawn of sulfanilamide chemotherapy. Since sulfanilamide and its derivatives have been available, about a dozen cases thus treated have been reported, without a fatality; all were marked by prompt and complete recovery.

In 1937, Schwentker, Gelman and Long<sup>3</sup> reported briefly a case of uncomplicated meningococcemia in a series of meningococcal infections, which was successfully treated with sulfanilamide. Zende and Greenberg<sup>4</sup> reported an uncomplicated case in which the patient, ill three weeks when treatment was begun, recovered rapidly. Dimson,<sup>5</sup> in 1938, used pyridine (M & B. 693), with recovery in six days after the beginning of treatment. Craven,<sup>6</sup> in 1938, reported rapid clearing of all symptoms with complete recovery in a man ill with uncomplicated meningococcemia for seven weeks before treatment was begun. Long and Bliss<sup>7</sup> briefly mention "five cases suffering from acute meningococcemia without signs of meningitis in whom intensive therapy with the drug gave excellent curative results." Binns and Clancy,<sup>8</sup> in 1939, reported 2 additional cases much like the others: a child of twelve years ill for two months, and a forty-five year old man ill for seven weeks, before accurate diagnosis was made. Both patients rapidly recovered after sulfanilamide therapy was begun. Levy,<sup>9</sup> in 1937, treated a two year-old girl with both subcutaneous and oral therapy for nine days, with spectacular results. Kattwinkel<sup>10</sup> recently reported a case in which, with justification, the diagnosis of gonococcemia was originally made; the patient, a twenty two year-old woman, recovered rapidly following adequate oral doses of sulfanilamide. An additional case is reported below.

## CASE REPORT

A 55-year-old woman was admitted to the hospital on February 29, 1940, complaining of chills and fever, marula-

papular lesions on the face, trunk and extremities, and joint pains.

On February 15, 1940, the patient went to bed feeling quite well. She was awakened during the night with a marked chill. She took some aspirin and went back to sleep. The next morning, she felt fairly well, except for a mild sore throat and a stuffy feeling in her nose. At noon, she was nauseated, and vomited, with relief. The next day, February 17, however, she had another chill and developed high fever, and pain developed in many joints. She was given large doses of salicylates and bicarbonate of soda. The following day, a maculopapular rash was noted on both legs below the knees. Every 2nd or 3rd day from that time on, she developed a severe chill followed by high fever, varying between 103 and 105.4°F, each fastigium being followed by a fresh crop of maculopapular lesions, which gradually appeared over the entire body, accompanied by exacerbations of the polyarthralgia. No heat, redness or swelling appeared in any joints. During the remissions of fever, the patient became surprisingly well. Urinalysis was normal, the white-cell count was 12,800, with 82 per cent polymorphonuclears. A blood smear was negative for malaria. On February 29, 2 weeks after the onset, she agreed to hospitalization. The past history was negative for rheumatic heart disease, and was otherwise not pertinent.

On admission, the temperature was 99.2°F, the pulse rate 110, the respiratory rate 20, and the blood pressure 102/60. Physical examination revealed a fairly well nourished and well developed middle aged woman in no acute distress. The skin showed many reddish pink macules and papules over the entire body, predominately on the legs, some of which faded on pressure. One lesion on the left ankle was crusted. The lesions varied in size from several millimeters to 1 cm in diameter. The older lesions were brownish. The eyes reacted normally to light and accommodation. The fundi were normal. There was no stiffness of the neck. The lungs were clear. The heart rate was rapid, but there were no murmurs, thrills or enlargement. The abdomen was normal, except for skin lesions and an old surgical scar. There was slight inguinal adenopathy. Neurologic examination was entirely negative, including tests of the cranial nerves and the sensory and motor systems. All reflexes were active, and the Kernig, Brudzinski and Babinski signs were negative.

The red cell count was 3,800,000 with a hemoglobin of 72 per cent, and the white-cell count 12,900 with 85 per cent polymorphonuclears. There were slight poikilocytosis, anisochromia, polychromia, no erythroblasts and normal platelets. The clotting time was 1 minute, and the bleeding time 2 minutes and 15 seconds. The sedimentation rate (corrected) was 0.7 mm per min. The blood Hinton reaction was negative, the nonprotein nitrogen of the blood serum was 27 mg and the blood sugar 71 mg per 100 cc. Urinalysis showed the slightest possible trace of albumin and no sugar, with rare red and white blood cells in the sediment.

\*From the Medical Department, Massachusetts Memorial Hospitals.  
†Instructor in medicine, Boston University School of Medicine, Visiting Physician, Massachusetts Memorial Hospitals.

Rheumatic fever, arthritic purpura, spotted fever, typhoid and undulant fever were considered, and blood was submitted to the laboratory. The patient meanwhile was given 60 to 90 gr. of salicylates daily, which controlled the joint pains quite well. These pains gradually subsided during the 1st week of hospital stay. On March 2, 4 and 6, the patient had further severe chills and high fever, new skin lesions following each attack.

Nose and throat cultures taken on March 7 were positive for *Micrococcus catarrhalis* on March 12. On March 7, the laboratory reported that the blood culture on February 29 showed meningococci, identified by sugar fermentations. The diagnosis was also checked by the Boston City Hospital laboratory. A second blood culture, taken March 7, was reported positive for meningococci on March 10.

Thirty grains (2.0 gm.) of sulfanilamide was given at once, followed by 20 gr. (1.3 gm.) every 4 hours. The blood sulfanilamide level was maintained between 11.8 and 14.3 mg. per 100 cc. from March 7 until March 15, although medication was reduced gradually from March 11 because of very rapid improvement. No further chills occurred, and the temperature never rose above normal after the beginning of sulfanilamide therapy; there were no further joint pains, and the skin lesions gradually disappeared. The white-cell count gradually dropped from 18,300 on March 5 to 10,000 on March 19. Two blood cultures, after sulfanilamide treatment had begun, were reported sterile. The patient received 905 gr. (60.3 gm.) of sulfanilamide, which she tolerated well, showing only moderate cyanosis. The drug was discontinued 13 days after therapy was begun. She was discharged from the hospital on March 23 without symptoms, 23 days after admission and 37 days after onset.

One year later, the patient was in excellent health.

## SUMMARY AND CONCLUSION

The literature on meningococcemia without meningitis is reviewed, and an additional case is reported. The diagnosis was obscure until verified by blood cultures in the third week of disease. All symptoms rapidly disappeared following sulfanilamide treatment.

The patients in the sulfonamide-treated cases of the disease thus far reported in the literature have all completely recovered promptly without sequelae.

Meningococcemia should be considered in any patient presenting symptoms of intermittent fever, unexplained rash and arthralgia.

# MEDICAL PROGRESS

## NUTRITION\*

HAROLD JEGHERS, M.D.†

BOSTON

THE purpose of this review is to emphasize, not the vitamins, — important though they are, — but the phase of nutrition that relates to national welfare, both present and future, and should be familiar to all physicians. In addition, several aspects of nutrition not commonly considered in reviews on deficiency disease are presented.

A rapidly increasing literature attests that the study of nutrition has passed the purely animal stage and is already deep into its application to human physiology and pathology. A number of the recent papers on this subject are purely inspirational and emphasize the lag between the accumulation and the practical application of nutritional knowledge.<sup>1-3</sup> Even the economic, social and political consequences that result from adequate or inadequate human nutrition are being considered.<sup>4-6</sup> World War II, with its mass experiments in malnutrition, and the defense efforts have stimulated an interest in nutrition never witnessed before in this country. Indeed, adequacy of nutrition may determine the political fate of a nation, as well as the physical well being and the morbidity and mortality of its people for a generation to come. The desire to have it favorably influence the Nation and the people becomes clearer each day.

### NATIONAL NUTRITION CONFERENCE FOR DEFENSE

The progress of nutrition in this country reached a pivotal point on May 26, 1941, when over eight hundred delegates (representing every interest in this field) met in Washington to attend the three-day National Nutrition Conference for Defense, called at President Roosevelt's request. The medical profession was well represented by noted nutritional authorities. Few such national conferences have been held, and none previously to discuss nutrition. Physicians may thus judge the import of this meeting. Procedures of the conference are not yet available, but a detailed review,<sup>7</sup> including parts of the original manuscripts, has been pub-

lished. Its scope is too vast for a complete analysis to be given. However, a few points will be presented so that its main objectives and far-reaching implications will be appreciated.

Brigadier General Lewis B. Hershey, deputy director of the Selective Service System, stated that, of 380,000 rejections for general military service, it had been estimated that perhaps one third were due either directly or indirectly to nutritional deficiencies. Paul V. McNutt, Federal Security Administrator, quoted President Roosevelt as emphasizing the present significance of the nutritional problem, as follows:

During these days of stress the health problems of the military and civilian population are inseparable. Total defense demands manpower. The full energy of every American is necessary. Medical authorities recognize completely that efficiency and stamina depend on proper food. Fighting men of our armed forces, workers in the industry, the families of these workers, every man and woman in America, must have nourishing food. If people are undernourished, they cannot be efficient in producing what we need in our unified drive for dynamic strength. . . . The Department of Agriculture has estimated that many millions of men, women, and children do not get the foods which science considers essential.

Surgeon General Thomas Parran summed up the American food situation in this way:

One half of our fuel — the calories we eat — is in the form of bread and sugar. Add to this the refined fats, and two thirds of our energy intake is in the form of "inert calories," which furnish fuel and nothing else. From the remaining third of our diet we must get the vitamin B complex and the minerals needed to burn up the inert calories. This is where we have been starving ourselves.

The Committee on Food Habits organized by the National Research Council will attempt by education and practical psychology to change the food habits of the public. Dr. Russell M. Wilder, chairman of the Committee on Foods and Nutrition, explained how the recent origin of scientific nutritional knowledge, the difficulty of recognizing minor clinical deficiencies and the prevalence of quackery and food fads in the nutritional field had made many physicians hesitate to apply the principles of nutrition in their practices. He ended his address with a plea to the physician to assume leadership in this field.

The conference made a number of specific recom-

\*All articles in this series will be published in book form in the current volume is *Medical Progress Annual 1940* (Springfield, Ill.) nos. 5 Charles C. Thomas Company 1941 \$4.00.

mendations to the President. Briefly, these were the use of the suggested nutritional yardstick (Table 1) as a goal for adequate nutrition; the translation of these allowances into units understandable by the laity; continued nutritional research; the education of all professional groups concerned with nutrition (that is, doctors, dentists, teachers and so forth); the education of the public in nutritional knowledge; the mobilization of any organized unit able to contribute to this campaign; the continued attack on fundamental prob-

formation becomes of more value in the practice of medicine than ever before. An editorial comment in the *Journal of the American Medical Association*<sup>8</sup> concerning this conference is well worth reading.

The highlight of the conference, so far as the practitioner of medicine is concerned, was the promulgation by the Committee on Foods and Nutrition of the National Research Council<sup>9</sup> of recommended daily allowances for the various dietary nutrients (the so-called "yardstick for good

\*Tentative goal toward which to aim in planning practical dietaries, can be met by a good diet of natural foods. Such a diet will also provide other minerals and vitamins the requirements for which are less well known.

†Requirements may be less if provided as vitamin A, greater if provided chiefly as the provitamin carotene.

‡1 mg thiamin = 333 int. units, 1 mg ascorbic acid = 20 int. units.

§Needs of infants increase from month to month, the amounts given are for approximately 6 to 8 months. The amounts of protein and calcium needed are less if derived from breast milk.

||Allowances are based on needs for the middle year in each group (2, 5, 8 and so forth) and for moderate activity.

¶Vitamin D is undoubtedly necessary for older children and adults, when not available from sunshine, it should be provided probably up to minimum amounts recommended for infants.

Reprinted, with slight modification, with the permission of Dr. Russell M. Wilder, chairman, Committee on Foods and Nutrition, National Research Council. Copies of this chart, with explanatory notes, can be obtained from Nutrition Division, Federal Security Agency, Washington, D. C.

lems of unemployment; the use of any practical device to bring foods to those otherwise unable to afford them, such as the so-called "stamp plan"; the improvement of food distribution; the encouragement of agriculture to a greater production of foods needed in abundance; the encouragement of more production for home use by rural people; and the enrichment of certain staple food products. The realization of these recommendations is certain to have a profound influence for the better on the future health of the Nation and will do much to improve the efficiency of the present defense effort. Nutritional in-

nutrition"); these allowances are given in Table 1. They represent the available scientific knowledge. Nutritional authorities were willing to accept the values tentatively until standards derived from more exact data could be obtained. Foods supplying adequate thiamin, riboflavin and nicotinic acid will tend to supply an adequate amount of the remaining components of the vitamin B group. Diets adequate in protein, calcium and iron will tend to supply other needed minerals, although these are not listed. Adult allowances are given for a man weighing 154 pounds (70 kg.) and for a woman weighing 123 pounds (56 kg.), at the

levels of physical activity, and should be proportionately increased or decreased for larger or smaller persons. Allowances for the vitamin B group are proportional to the caloric intake, and apply to healthy persons, disease may alter them considerably. It is of interest that the protein requirement does not increase with activity in adults. It is increased during pregnancy and lactation, and for children and adolescents. Calcium requirements are discussed in detail elsewhere in this paper. The committee expects nutritional workers to translate these scientific terms into appropriate quantities of foodstuffs available in their own locality and to meet special situations.

The various nutrients provided for in these allowances, with the exception of vitamin D, can be obtained through a diet of natural foods or foods enriched according to the committee's recommendation. Translation of these allowances into a daily dietary pattern of actual foods is given in Table 2. This is an excellent list for the physician

1 demonstrates the nutritional inadequacy of white flour. The superior taste and appearance of white bread originally dictated this change. The nutritional error thus committed did not become apparent until about 1920, and only recently has its full import been appreciated by nutritional experts.<sup>1, 10, 11</sup> In the meantime, several generations

TABLE 2 *Dietary Pattern Suggested by the Committee on Foods and Nutrition, National Research Council<sup>9</sup>*

Food	AMOUNT
Milk	Adults 1 pint children 1/2 pint daily
Egg	Three or four times per week
Meat	One serving (30 gm) at least up to 90 years (for adults)
Vegetables	Two servings (one green or yellow)
Fruit	Two servings (one citrus or banana)
Potato	One or more servings
Ber or fortified oil	100-500 calories
Whole grain or enriched cereal and bread	At least half the intake
Salt and so forth	To complete the caloric requirement

to keep in mind when he attempts to evaluate the adequacy of his patient's diet. It is well to note that half the caloric intake is of whole grain or enriched cereal and bread, and that specific minimums for milk intake are given.

#### NUTRITIONALLY IMPROVED OR ENRICHED FOODS

The introduction of steel roller milling of wheat some seventy years ago cheapened the cost of producing white flour and resulted in its displacement of whole meal flour. Nutritional loss to the public resulted, inasmuch as white flour contains almost no vitamin E and less protein, calcium, phosphorus, iron, vitamin B complex, and carotene than whole meal flour.<sup>10</sup> White flour has been used not only for bread, but for cakes, pies, gravies, sauces, crackers and so forth, and contributes 25 per cent or more to the average daily caloric intake. A comparison of the ingredients of nutritional value of white flour with whole wheat flour is given in Table 3. A further comparison of this table with the requirements listed in Table

have accepted white flour as a major item in their diet and have become accustomed to its use.

Most of the sugar used in this country is refined and hence devoid of minerals and vitamins. The daily per capita consumption of sugar is said to average about 155 gm, which represents 600 calories, or one fourth of all the calories of the diet.<sup>1</sup> Last year, only one fourth of the margarine in the United States was fortified with vitamins.<sup>2</sup> Lard and polished rice, likewise poor vitamin sources, are used extensively.

It is a nutritional fallacy to teach that the balance of the American diet, even if good natural foods are used, will compensate for this 50 per cent or greater caloric content lacking in minerals and vitamins. Reference to Table 2 which lists a truly adequate diet, makes this point clear. Each food is expected to carry its own weight in contributing to the adequacy of the total diet.

The eating habits of the American public are now so well established that a worthwhile change, although not impossible, would be slow. Some favor education of the public to the use of natural foods.<sup>12</sup> The present world crisis makes it imperative that this country secure, as rapidly as possible, the benefits to accrue from application of nutritional knowledge. To this end, fortification or enrichment of foods with nutritional ingredients lost in the manufacturing process is considered a worthwhile solution.<sup>13, 14</sup> Wilder<sup>1</sup> has discussed the inadequacies of solving this problem by urging the public to consume vitamin and mineral pills.

Fortification of food is by no means a new or

untried procedure. Over fifteen years ago, salt was fortified with iodine in the endemic goiter regions, with excellent prophylactic results.<sup>2</sup> Fortification of foods with vitamin D has reduced the incidence of rickets.<sup>2</sup> Fortification of margarine with vitamins A and D was made compulsory in Denmark years ago<sup>1</sup> and has already been used with some of the margarine sold in this country.

The possibilities of enrichments of flour and bread have aroused much interest and comment, as well as some criticism both in this country<sup>1, 7, 11, 13</sup> and in England.<sup>16-18</sup> The Council on Foods and Nutrition of the American Medical Association has recently submitted a detailed report on this subject.<sup>19</sup> There is much to be said in favor of using only natural unrefined foods.<sup>12</sup> However, many objections have arisen to this proposal. In brief, time would be required to change the people's food habits; many do not like the taste or appearance of dark bread; others must avoid the effect of its roughage on their gastrointestinal tract; the baking qualities are not so good as those of white flour; whole-meal flour does not keep so well; and much money is now invested in milling equipment for preparing white flour.<sup>1, 2, 7, 10, 11</sup> One may expect to see the fortification of flour practiced extensively in the future. The British have already fortified their white flour with calcium, iron and thiamin.<sup>16, 18</sup> Fortification of flour is more advantageous than direct fortification of bread, since flour is widely used for other purposes besides bread.

Table 3 gives the average composition of whole-wheat and white flour and, for comparison, the minimum and maximum degrees of enrichment of flour according to the definition and standard proposed by the United States Food and Drug Administration. In principle, this has been endorsed by the Council of Foods and Nutrition of the American Medical Association and by the Committee on Food and Nutrition of the Division of Medical Sciences of the National Research Council. The reason for each figure given is discussed in detail in the council's report.<sup>19</sup> Briefly, the council sponsors "fortification with a limit, that limit being the content of the natural or unprocessed foods." Standards for enriched bread as suggested by the Committee on Food and Nutrition of the National Research Council are given in Table 4. Thus, white bread, with no change in taste or appearance, will approach whole-wheat bread in nutritive qualities. New milling techniques, which preserve more of the original nutritive ingredients of wheat and still produce a white flour, have been perfected, and will be further improved with time. The vitamin B complex of

bread could also be fortified with more nutritious forms of yeast.<sup>19</sup>

Wilder<sup>1</sup> has made several suggestions. If each average daily per-capita portion of sugar (155 gm.) were fortified with slightly more than 30 gm. of skimmed-milk solids, the average American diet would be improved by the addition of the equiva-

lent of a pint of skimmed milk. The edible fats, margarine and lard, can be fortified with vitamins A and D. Ascorbic acid is sensitive to oxidation and heating and is therefore less well suited for fortification. However, citrus fruits, tomatoes and potatoes—good to fair food sources of vitamin C—are plentiful in this country. Irradiation of food, to increase its vitamin D content, is already widely practiced. The many suggestions for fortifying foods with calcium are discussed below.

#### NUTRITIONAL ASPECTS OF CALCIUM

In contrast to the many publications dealing with vitamins is the comparatively modest but nevertheless important literature concerned with the nutritional aspects of calcium. With almost no exception, these papers stress the frequent inadequacy of this substance in the American and English diet.<sup>20-23</sup> In fact, the investigative methods of one of the few recent papers<sup>24</sup> to contradict this point of view were immediately criticized, and its results discounted.<sup>25-27</sup> Although realizing the significance of an adequate calcium intake for infants and young children, few physicians have paid much attention to the calcium intake of adults. The metabolism of calcium, phosphorus and vitamin D is closely related and interdependent. Phosphorus is present in many foods, so that diets are rarely deficient in this substance. Foods adequate in protein contain sufficient phosphorus. In fact, no specific mention of phosphorus requirements was given at the National Nutrition Conference (Table 1). Practically none of the common foods are adequate in vitamin D. Infants and children now almost universally receive fish-liver oil, viosterol or irradiated foods to supply this deficient vitamin. And its use during pregnancy and lactation is rapidly increasing. Adults

with no opportunity for exposure to sun may require supplementation of their diet with vitamin D (Table 1).

Of the aforementioned triad, calcium is the substance that is likeliest to be deficient in the average diet; rarely is an attempt made to remedy this fault.

Of the total calcium content of the body, 99 per cent is contained in the bones, none in the red blood cells, a small amount in tissue fluids and 9.5 to 11.5 mg. in each 100 cc. of blood serum.<sup>28, 29</sup> The necessity of the blood calcium for normal neuromuscular irritability, clotting of blood and so forth is too well known to require comment.

Active adults with normal endocrine and renal function, an adequate supply of vitamin D and proper intestinal absorption maintain a normal blood-calcium level regardless of the adequacy of the dietary calcium; calcium is removed from the trabeculae of the bones when the calcium balance is negative and stored when the supply is great.<sup>28</sup> Urinary and stool excretion of calcium continues, even when the dietary intake of calcium is low or absent. The influence on bone metabolism of long-continued dietary calcium deficiency, with resultant negative calcium balance, has aroused much interest in recent years.<sup>30-34</sup> Vitamin D and a sufficient amount of phosphorus are essential for the proper metabolism of calcium, as is normal parathyroid function. The presence of hydrochloric acid, sucrose, lactic acid and citric acid in the gastrointestinal tract favors calcium absorption.<sup>22, 35</sup> Alkalies, excess fats, excess phosphates, oxalic acid (present in leafy vegetables), maltose and starch interfere with its absorption.<sup>22</sup> The phytic acid of cereals was formerly believed to immobilize calcium.<sup>35</sup> However, in more recent studies, calcium phytate proved to be readily absorbed.<sup>36</sup> By interfering with the utilization of vitamin D, the ingestion of mineral oil in growing dogs has been found to result in poor retention of both calcium and phosphorus, with the development of rickets.<sup>37</sup> This may or may not be of clinical significance. The ration used contained 5 to 10 per cent mineral oil, proportionally more than is likely to be used by human beings. All this emphasizes the complexity of the problem of calcium absorption and the need for a safe margin over the amount estimated for maintenance requirements. At best, only 20 to 30 per cent of calcium ingested by adults and older children is utilized.<sup>33</sup>

Milk and cheese are the only good sources of calcium in the diet, and in their absence it is exceedingly difficult to fill the calcium need through

food alone.<sup>22</sup> The inadequacy of calcium in other foods is well illustrated in a table prepared by Bernheim.<sup>22</sup> To secure 0.70 gm. of calcium daily from any other single food, it would be necessary to eat 3.2 lb. of beans, 7.3 lb. of white bread, 5.5 lb. of brown bread, 11.0 lb. of butter, 1.5 lb. of cauliflower, 27.5 lb. of corn, 20 eggs, 2.3 lb. of oatmeal, 17.0 lb. of potatoes, 4.9 lb. of oranges, 26.4 lb. of lean meat, 14.7 lb. of fish and so forth. Furthermore, the oxalic acid present in some leafy vegetables prevents adequate absorption by the formation of insoluble calcium oxalate in the intestinal tract.

A quart of milk contains slightly more than a gram of calcium (1.16 gm.)—a useful figure to commit to memory. An economical source of milk looms large as a factor in arranging for an adequate supply of calcium in diets of persons in the low-income group.<sup>38</sup> Koehn<sup>39</sup> has some interesting recommendations in this regard. A 1¼-in. (3.2-cm.) cube (30 gm.) of yellow cheese may be substituted for half a pint of milk. This contains about 0.25 gm. of calcium. Skimmed milk or butter-milk is the equivalent of whole milk in calcium and protein, but not, of course, in fat or the fat-soluble vitamins, and is much cheaper.<sup>39</sup> Both are excellent sources of calcium for persons attempting to lose weight. Evaporated milk is the equivalent of whole milk in calcium content and is less expensive. Dry skimmed milk (dry milk solids) has the food value of whole milk, except for the fat, and is cheaper. One quarter of a pound (120 gm.) of dry skimmed milk, diluted with water, makes a quart of fluid skimmed milk. Milk used in cooking, desserts made from milk, ice cream, because of milk content, and so forth, add to the calcium content of the diet. For all practical purposes, a check on the calcium content of a patient's diet concerns information on the use of these items.

From the evidence already presented, the frequency of calcium deficiency in the American diet becomes understandable. Serious consideration has been given to various plans to increase the calcium content of staple foods. The supplementation of white flour with calcium, to a maximum of 2000 mg. per pound (Table 3), is one proposal. The addition of milk solids to cane sugar is another.<sup>1</sup> The British have already added 7 ounces (210 gm.) calcium carbonate (*creta praeparata B.P.*) to each 280-pound sack of white flour used in the preparation of their so-called "war loaf." Fortification of breakfast cereals with calcium is another suggestion. For example, Pierce and others<sup>40</sup> found that when part of the milk calcium of an adequate diet fed to children was re-

placed by an equivalent amount supplied by tricalcium phosphate in a fortified cereal, utilization as measured by retention was equally good from milk and cereal.

Furthermore, direct supplementation of the diet with one of the calcium salts is entirely possible if an adequate supply of food calcium is lacking. A number of studies indicate that this substitution is practical on an extensive scale. Aykroyd and Krishnan<sup>41</sup> during a four-month period gave children (ages two and a half to seven) in a nursery school in South India 0.5 gm. of calcium lactate daily. The children showed greater increases in weight, height and general well-being than a control group of children in the same school who did not receive the supplement. These authors recommend that calcium salts be used as a partial substitute for milk when the latter cannot be obtained. Gaunt and his associates<sup>42</sup> had previously shown that improvement exhibited by a large colony of rats (reared for generations on an average diet eaten by a working-class community in Scotland) when greens and milk were added to this diet could be duplicated in large part by adding mineral supplements of calcium and phosphorus. In human practice, increased consumption of milk was recommended as the best means of improving the diet whenever it was possible.

Gunderson<sup>43</sup> discusses the economics of the use of calcium salts. Precipitated calcium carbonate is listed as the most economical source, calcium gluconate as the most expensive. Calcium triphosphate, calcium phosphate (bone meal), calcium diphosphate, calcium monophosphate, calcium citrate and calcium lactate range between these in this order.

The calcium requirements for human beings have been worked out by means of calcium and phosphorus studies, the presence and degree of positive or of negative calcium balance for various levels of calcium intake being determined. In addition, the rate of growth and weight of the skeletal structure has been considered. Leitch<sup>44</sup> reviewed the literature dealing with this subject. By such means, the minimal or maintenance requirement for calcium is determined. Optimal requirements used for clinical purposes are determined by adding 50 per cent to this minimal level to allow for possible difficulties in utilization (as was noted above in the discussion on the absorption of calcium).

For many years, Sherman's<sup>23</sup> estimate of 0.45 gm. of calcium as the minimal and 0.70 gm. as the optimal daily requirement for an adult weighing 154 pounds (70 kg.) was the accepted standard. Owen<sup>45</sup> found 0.52 gm. to be the minimum,

whereas Leitch,<sup>44</sup> from an extensive survey, gave 0.55 gm. as a minimum. The optimal daily allowance for calcium as recommended by the Committee on Foods and Nutrition of the National Research Council is given in Table 1: 0.8 gm. for adult men and women, 1.5 gm. during pregnancy, 2.0 gm. during lactation, 1.0 gm. for small children, and 1.3 to 1.4 gm. from puberty until growth is completed.

The greater need for calcium during the years of growth, pregnancy and lactation should be constantly kept in mind. The difficulty of sustaining lactating women in a positive calcium balance has been emphasized.<sup>46</sup> The calcium problem in obstetrics has been discussed by Bear<sup>47</sup> and by Mendenhall and Drake.<sup>48</sup> The diet during puberty needs special attention. In a survey in Toronto among families able to supply a reasonably good diet, the lowest intake of calcium and milk was found in the girls in their teens, explainable on the current desire of girls to be slim.<sup>49</sup> McHenry urges that this group be educated to realize that an adequate knowledge of nutrition allows one to avoid obesity and still to be properly fed. Skimmed milk or dry milk solids may be substituted for whole milk if the fear of obesity causes the latter to be omitted from the diet.

What ill effects are to be expected when adults live for years on a diet deficient in calcium? Many recent papers<sup>30, 32, 34, 44</sup> have attempted to correlate the considerable incidence of osteoporosis among persons past middle life with this factor. Nervous irritabilities have likewise been attributed to this cause.<sup>30</sup> However, the cause of senile osteoporosis is by no means settled. Among the possible explanations are: long-continued dietary calcium deficiency, with negative calcium balance and gradual demineralization of the skeleton<sup>31</sup>; deficiency of vitamin D<sup>33</sup>; inability to absorb mineral salts from the gastrointestinal tract with advancing years<sup>33</sup>; the presence of achlorhydria in old age<sup>32</sup>; atrophy of bone due to disuse as the result of restricted physical activity in old age<sup>50</sup>; and senescent changes.<sup>50</sup>

Albright and his co-workers<sup>50</sup> have described postmenopausal osteoporosis, a form of bone disease often confused with senile osteoporosis, and attribute it to the endocrine changes following the menopause. A beneficial effect of estrogen therapy on the retention of calcium in this condition was noted. They consider osteoporosis a disease in which the osteoblasts are primarily deficient in laying down osteoid tissue, and believe that a negative nitrogen balance may interfere with osteoblastic activity in laying down the necessary organic matrix. Such a factor could well be present

in old age. Adequacy of protein in the diet thus becomes a factor to be considered in the etiology of senile osteoporosis.

Owen, Irving and Lyall<sup>34</sup> made calcium balance studies of 7 male patients over seventy years of age; 4 of them manifested osteoporosis by roentgenographic examination. Three were in calcium equilibrium with intakes of only 0.3 gm calcium. The authors believe that their results suggest adaptation by the body to the continued smaller calcium intake by a lower rate of calcium turnover and a lessened reserve of calcium in the skeletal stores; they conclude that prolonged nutritional calcium deficiency may result in generalized osteoporosis in elderly patients. Leitch<sup>44</sup> subscribes, in part at least, to the theory that senile osteoporosis is due to prolonged calcium deficiency. The study of Adams, Boothby and Snell<sup>51</sup> indicates that treatment of senescent osteoporosis with calcium salts can convert a negative calcium balance to a positive one and thus store calcium and phosphorus. Their subject, a sixty-five-year old woman with osteoporosis, stored over a nineteen week period 29.3 gm. of calcium and 13.3 gm of phosphorus, a ratio of 2.2:1—or the ratio of these substances in bone.

These studies seem to indicate that adequate calcium, protein and vitamin D nutrition throughout life may prevent the development of osteoporosis in old age. Furthermore, treatment of senile osteoporosis with a diet adequate in protein and calcium, supplemented with calcium and phosphorus salts and vitamin D, has some rationale as a therapeutic procedure. To be successful, it will probably have to be continued for a long time.

The nature and the amount of the dietary intake of calcium, aside from its purely nutritional aspects, are often of diagnostic or therapeutic interest in the practice of medicine. For example, in using the Sulkowitch reagent to test for calcium in the urine, one should remember that normal persons may show excess urinary calcium shortly after drinking a large amount of milk.<sup>29</sup> This may be confused with hypercalciuria due to disease. Albright,<sup>29</sup> in discussing the treatment of hypoparathyroidism, stresses the need for a high intake of calcium and a low intake of phosphorus, but adds that, in spite of its high calcium content, milk is contraindicated because it is likewise high in phosphorus. Persons with prolonged recumbency and immobilization of the body because of injury or disease often have hypercalciuria due to demineralization of the skeleton, with the formation of renal calculi. Carlson and Ockerblad<sup>52</sup> point out that the use of much milk, the basis of most sickroom diets, often leads to excessively high calcium intakes, which become an additional

factor to be considered under such circumstances in explaining the calculus diathesis. Barney and Jones<sup>53</sup> suggest that ingestion of excessive amounts of milk and cheese, especially when the urine is alkaline, may, by precipitating calcium phosphate in the urine, be a factor in the formation of calculi in the urinary tract. Kempster and others<sup>54</sup> recommend that persons allergic to milk secure their daily calcium requirement as dicalcium phosphate, with a percentage utilization equal to the calcium in milk. Albright<sup>29</sup> has emphasized the fact that the characteristic bone changes of hyperparathyroidism may be lacking if the patient's diet has contained sufficient calcium to balance the excess urinary calcium loss. Such persons are invariably heavy milk drinkers. Diagnosis then rests on the chemical findings in the blood, the presence of renal calculi, systemic symptoms and so forth.

### NUTRITION IN OLD AGE

Many publications have appeared in recent years stressing the importance of the study of disease in old age. In fact, the rise of the specialty of geriatrics—the old-age counterpart of pediatrics—is foreseen,<sup>55</sup> a possibility by no means unlikely in view of the increasing proportion of older people in this country's population. Official cognizance of the senescent individual in the national life and economy was recently taken by the United States Public Health Service with the establishment of a Unit of Gerontology at the National Institute of Health.<sup>56</sup> Under the editorship of Cowdry,<sup>57</sup> the known facts concerning the aging process have been reviewed.

Sherman<sup>58</sup> believes that the nutritional knowledge already available will, if properly applied, “add life to our years,” and “. . . add years to our lives.” Food and nutrition have now been accorded a place, along with heredity, in the control of longevity. The praiseworthy results of the increasing appliance of the nutritional principles in the practice of pediatrics are too well known to need any comment. One already finds cautious suggestions<sup>1, 2, 3, 59</sup> that long continued inadequacy of diet may be a factor in the early development of degenerative diseases. Naturally, to be truly effective, such dietary principles must be applied early in life. Harris<sup>60</sup> aptly emphasizes the fact that the effective practice of geriatrics must begin where the pediatrician leaves off. The effects of a lifetime of unhygienic habits and an incorrect diet cannot be righted, once old age is reached. The practitioner of medicine—the family doctor—is thus entrusted with the promulgation of this thesis. An inquiry into a per-

son's habits of eating and recommended dietary changes, as the circumstances require, may well become a routine part of the annual health check-up now being widely recommended to the public by many agencies.

Diminution of appetite is common in old age, and its causes and remedies have been discussed by Meyer.<sup>61</sup> This, coupled with the fact that many elderly people because of loss of teeth and inadequate artificial dentures are unable to chew properly, frequently marks the onset of a poor dietary regime in old age. The latter cause is commonly responsible for the clinically detectable deficiencies noted in old people studied on the medical wards of the Boston City Hospital.<sup>62</sup> Meyer and his co-workers<sup>63</sup> found that old people have less salivary secretion of ptyalin than young adults, with resultant deficiency of starch digestion in the mouth and stomach. Whereas 50 gm. of white bread is easily digested in the mouth and stomach of young people, only 0.5 gm. is digested by old people.<sup>63</sup> Masticatory difficulties in old age often necessitate a soft diet, relatively high in carbohydrates and low in protein. However, the same workers<sup>64, 65</sup> found in a later study that the total intestinal digestion of carbohydrates was not markedly disturbed, because the pancreatic amylase, although slightly subnormal, was sufficient to complete this digestive process. They occasionally noted, in fact, abnormally high values for this pancreatic enzyme in the age group from eighty-one to one hundred years. These levels were considered to be possibly compensatory for the lowered salivary ptyalin of old age. Both proteolytic enzymes (pepsin and trypsin) were found to be diminished in old age, but they concluded that the concentration was adequate to meet the requirements of the usually decreased protein intake. They admit, however, that some old people consume large quantities of protein, with apparently normal digestion. They conclude their paper by stressing the fact that such studies may be helpful in rationalizing the dietary management of old persons.

The incidence of achlorhydria is known to increase with advancing age.<sup>66</sup> The influence of achlorhydria on the absorption of various substances in the diet and their utilization by the body may be important. Its interference with the absorption of iron has been established. Less is known of its influence on the absorption of fractions of the vitamin B complex and other dietary factors. Leitch<sup>44</sup> comments on the need for more knowledge of its relation to the absorption of calcium, a subject worthy of investigation, in view of the frequency of osteoporosis in old age.

Interference with eating in old age commonly results from digestive symptoms. Meyer<sup>61</sup> stresses their frequency, and emphasizes that cardiac, renal and hematologic disorders, all particularly common at this time of life, may be factors in producing such symptoms, apart from diseases primary in the gastrointestinal tract. Physiologic changes incident to the aging process are undoubtedly additional factors in causing such symptoms. All this serves to emphasize again that maintenance of adequate nutrition is often more difficult in old age than in early life.

Tuohy<sup>67</sup> found that undernutrition in the aged was more frequently the result of perverseness of appetite than economic adversity. He noted that old people often limit their diet because of faulty advice or inherent fear of eating adequately. The *Journal of the American Medical Association*<sup>68</sup> has commented editorially on this subject.

Owen<sup>15</sup> and Robertson,<sup>69</sup> from calcium balance studies on old men, found their requirements to be much the same as those of young adults, with a further similarity that they readily retained calcium and phosphorus after depletion. Increasing age did not offset long subjection to a diet low in calcium.

The significance of long-continued negative calcium balance on the genesis of senile osteoporosis has already been discussed.

The average 10 per cent reduction in the basal metabolic rate of old age<sup>70</sup> and the lowered physical activity indicate the need for reduction in caloric intake. The adverse influence of obesity on longevity is well recognized. The diet of old age must therefore be planned to avoid this factor and eliminate it if it is already present.

Vitamin deficiencies, especially of minor degree or with atypical manifestations, are common in old age.<sup>67</sup> Tuohy<sup>67</sup> remarks that gastrointestinal atony may respond to the use of thiamin. Mental changes often ascribed to the aging process may be due to nicotinic acid deficiency.<sup>71</sup>

Piersol and Bortz<sup>72</sup> suggest the use of liver twice weekly, in addition to iron-rich foods, to maintain the red-cell count at a normal level; milk is urged as an ideal food for old age. They also comment that a minimum fat content is in order. Horn<sup>73</sup> likewise considers fats to be the least of the dietary essentials of old age. Tuohy<sup>74, 75</sup> extols the high-protein diet in old age as protective against inadequate hematopoiesis and, indirectly, liver insufficiency. He also urges a freer diet and less fear of food with old people.<sup>67</sup> Barovsky<sup>76</sup> reports that milk fortified with minerals and vitamins was well tolerated by a group of 30 senile persons. Tuohy<sup>67</sup> reports that arteriosclerotic persons often

tolerate several light meals better than a smaller number of heavy ones

One may conclude from these papers that persons in the old age group can often support an adequate diet. Such a diet should be of low caloric content, with a minimum of fat, and adequate in protein, it should contain liver and iron rich foods and, above all, milk. The last may be given as skimmed milk if the fat content is to be avoided. Adequate intake, if necessary by supplementation, of all the vitamins is much to be desired. Since old people have but little exposure to sun, the addition of vitamin D should not be overlooked. Smaller and more frequent meals are often required. If the teeth are absent special care is needed to prevent inadequacies of the diet. Under such circumstances, milk becomes of even greater benefit as a primary food. Osteoporosis of old age may be preventable under such a regime.

#### MISCELLANY

Bourne's book, *Nutrition and the War*, an English publication, is typical of several that attempt to educate the public in the essentials of nutrition and thus to prepare them to make the most nutritionally of every food, should the supply and variety be curtailed by war conditions. Familiarity with such material will enable physicians to give dietary advice in terms that the average layman can appreciate and understand. American physicians are not faced with the practical realities of this problem as their British colleagues are. The papers by Booher<sup>8</sup> and Koehn<sup>9</sup> give some excellent practical advice on the economic aspects of diets as related to conditions in this country.

Orr<sup>7</sup> discusses a hypothetical wartime diet for the general population of England that illustrates the possibility of making a satisfactory diet from a small number of foods, many of which could be produced in England. Of interest is the fact that this limited diet would be more adequate than the prewar diet of the poorest 10 per cent of the population. The study points out that all the nutrients required by the body can be obtained from a few foodstuffs. This wartime diet consists of a daily ration of 0.6 pint (300 cc) of milk, 6 ounces (180 gm) of vegetables, 16 ounces (480 gm) of potatoes and 2 ounces (60 gm) of oatmeal,—is protective foods,—and 11.8 ounces (350 gm) of bread, 1.8 ounces (55 gm) of fats and 1 ounce (30 gm) of sugar—as energy yielding foods. An important objective of such a diet is to supply protective foods first, then as many energy yielding foods as are required to complete the desired caloric intake. Restrictions, if necessary, should apply to the latter first. Heavy work and army duty

would, of course, require the above diet to be increased.

Drazin<sup>80</sup> reviews representative examples of diets from various parts of the world to illustrate that monotony in diet is not detrimental to good health provided it is adequate from a nutritional viewpoint. As advantages for such a diet, he lists inexpensiveness, less trouble in preparation and less conduciveness to overeating, with resultant obesity and other metabolic disorders. Such statements are reassuring in the event that the variety of foods should be curtailed because of war conditions.

Except for iodine, which is required for proper thyroid function, and possibly copper, the significance of the so called 'trace elements' in the diet is not well established. Evidence indicates that they may be indispensable constituents of intracellular enzyme systems. Underwood,<sup>81</sup> Shohl<sup>82</sup> and Daniel<sup>83</sup> recently reviewed this subject and have listed detailed bibliographies. No direct clinical application to nutrition is in order at this time.

The influence of heating,<sup>11, 84</sup> canning,<sup>11</sup> and quick freezing<sup>85</sup> on the nutritive value of foods has continued to receive attention. It is of interest that the values recommended by the National Research Council (Table 1) refer to the amount of each factor actually eaten and make no allowance for extensive losses in cooking.<sup>9</sup>

The soybean is a new addition to the dietary of this country and is gaining rapidly in popularity.<sup>86, 86</sup> It is an unexcelled substitute for meat, its 36.5 per cent protein being of a variety closely resembling animal protein. It also contains about 20 per cent fat and 20 per cent carbohydrates.<sup>80, 86</sup> Soybean flour in any proportion up to 30 per cent can be used with white or whole wheat flour.<sup>81</sup> The Germans are reported to be using it extensively in various forms—the so called 'Nazi food pills'—as in army ration.<sup>87</sup>

Bourne<sup>88</sup> discusses the 'satiety value' of foods and points out that it is no indication of their nutritional value. Hunger is rapidly satisfied by sugar, butter, fatty foods, milk, potatoes, meat and eggs, but poorly satisfied by bread, green vegetables and nonfatty fish. As is well known, satisfaction of 'hollow hunger' is no guarantee of good nutrition. It must, however, not be neglected in planning any dietary regime. Hungry people are neither content nor efficient.

Johl and Cluver,<sup>89</sup> in a comparative study of the growth of physical efficiency of children from poor homes as contrasted with those from economically better situated homes, found no difference in the prepubertal age group but a striking difference in

favor of the latter after puberty. They concluded that, in the absence of true clinical deficiency, undernutrition of lesser degrees did not impair the growth of physical efficiency in the early years of life. However, the additional strain occasioned by bodily changes at the time of puberty caused a distinct lessening of the growth of physical efficiency unless the quality of the diet was improved. Table 1 shows the increased nutritional requirement at puberty suggested by the Committee on Foods and Nutrition of the National Research Council. Physicians responsible for the care of children should impress parents with the necessity of this dietary change at the time of puberty.

Many physicians find it difficult to avoid loss or interruption of sleep, long hours of work, nervous tension and improper care of their own minor ailments. However, adequate nutrition is within the grasp of each one. Olmsted<sup>90</sup> has written an interesting paper concerning the diet of the doctor. He believes that physicians who have good nutritional habits are sound advisers to their patients on this matter, and it affords them at least one opportunity to practice what they preach.

Sinclair<sup>91</sup> has reviewed the nutritional significance of fat in the diet. Reduction of fat in the diet when the caloric value is obtained mostly from crude high-carbohydrate foods—a situation common in Europe today—results in premature hunger and a reduced capacity to do sustained work. Wilder<sup>92</sup> also discusses the reality of "fat hunger." The per-capita consumption of fat in the occupied European countries is now less than 30 gm.,—less than one quarter of the prewar level,—for the German people 60 gm. and for the German soldier 90 gm. The fat supply is ample in this country.

favor of the latter after puberty. They concluded that, in the absence of true clinical deficiency, undernutrition of lesser degrees did not impair the growth of physical efficiency in the early years of life. However, the additional strain occasioned by bodily changes at the time of puberty caused a distinct lessening of the growth of physical efficiency unless the quality of the diet was improved. Table 1 shows the increased nutritional requirement at puberty suggested by the Committee on Foods and Nutrition of the National Research Council. Physicians responsible for the care of children should impress parents with the necessity of this dietary change at the time of puberty.

Many physicians find it difficult to avoid loss or interruption of sleep, long hours of work, nervous tension and improper care of their own minor ailments. However, adequate nutrition is within the grasp of each one. Olmsted<sup>90</sup> has written an interesting paper concerning the diet of the doctor. He believes that physicians who have good nutritional habits are sound advisers to their patients on this matter, and it affords them at least one opportunity to practice what they preach.

Sinclair<sup>91</sup> has reviewed the nutritional significance of fat in the diet. Reduction of fat in the diet when the caloric value is obtained mostly from crude high-carbohydrate foods—a situation common in Europe today—results in premature hunger and a reduced capacity to do sustained work. Wilder<sup>92</sup> also discusses the reality of "fat hunger." The per-capita consumption of fat in the occupied European countries is now less than 30 gm.,—less than one quarter of the prewar level,—for the German people 60 gm. and for the German soldier 90 gm. The fat supply is ample in this country.

DR. TRACY B. MALLORY: He had it nine years before entry and again on entry; that is the extent of our information.

DR. BAUER: Do you know anything about the initial illness? Did he have fever or jaundice, and why was he kept in the hospital so long?

DR. MALLORY: I cannot answer the questions.

DR. BAUER: The rash resembling hives is of no diagnostic help to me. Did this man ever have any symptoms suggesting duodenal ulcer?

DR. MALLORY: I do not know.

DR. LOWREY F. DAVENPORT: The best story came from the outside doctor, who followed the case for fifteen years and was convinced that the bleeding nine years before entry was quite typical of ulcer; x-ray examination in several places confirmed the diagnosis. The patient had had a protuberant abdomen for years, and because of this we had a great deal of difficulty persuading him to come to the hospital. He said that his abdomen had always been large, and not until we showed him that his trousers lacked 10 inches of meeting was he convinced that he was unusually large.

DR. BAUER: He had a swollen abdomen. We do not know how much significance to attach to the abdominal findings, because determining the size of the liver and spleen under these conditions is always difficult.

Patients with cirrhosis may require innumerable paracenteses over a period of years. It is possible to have ascites due to portal obstruction for a period of nine years. On the other hand, unless the history is very inadequate, the patient was extremely well between the episodes of gastrointestinal bleeding; I should therefore be inclined to believe that there were times when he had little or no ascites.

The chest signs, I presume, were consequent to the large amount of ascitic fluid.

The temperature of 104°F. is probably of significance, particularly in that we are dealing with a man who had what would seem best interpreted as portal obstruction. He obviously had suffered from gastrointestinal bleeding from time to time, and this was the reason for his seeking hospital admission. That he was jaundiced is shown by the van den Bergh reaction.

The ascitic fluid, from the information given, seems to have been a transudate rather than an exudate. Was it by any chance injected into a guinea pig?

DR. MALLORY: No.

DR. BAUER: A roentgenogram subsequent to the injection of Thorotrast showed very little increase in density of the liver. This finding would be in keeping with the diagnosis of chronic liver

disease, such as cirrhosis, because Thorotrast is taken up by the reticuloendothelial system. If the liver is diseased, one expects a reduction in that system and, consequently, no increase in density of the liver, following the injection of this substance.

Have we the x-ray films here? Is there any suggestion of pulmonary disease? Is there any reason to believe that the patient had tuberculosis?

DR. JAMES R. LINGLEY: The lungs are clear, except for this atelectasis at the base, as described. The diaphragm is high on both sides, probably because of ascites, and this leads to some compression atelectasis at the bases, more marked on the right. The lungs are otherwise clear. The aorta is quite tortuous. This is the area referred to in the inferior margin of the glenoid fossa, about which I cannot help you very much. The changes are very indefinite. The first thing I should think of is Paget's disease, but it could be metastasis.

DR. BAUER: Is there any reason to suspect tuberculosis?

DR. LINGLEY: No; this is the abdominal film, showing the spleen enlarged and increased in density by Thorotrast. The liver, on the other hand, is much less dense than the spleen. It should be denser after Thorotrast. It does not appear to be enlarged.

DR. BAUER: You do not think this could be an end result of septic arthritis some years previously?

DR. LINGLEY: The changes are too localized, and there is no narrowing of the joint spaces.

DR. BAUER: Do you think that the bone is denser here than here?

DR. LINGLEY: It looks a little irregular and increased in density along the margin. I should put Paget's disease first.

DR. BAUER: I should think there was little doubt that we are dealing with a man who had physical findings consistent with portal obstruction due to cirrhosis of the liver. In addition, he had a suppurative, cervical adenitis. The very fact that the latter had been present on two occasions previously and had been incised some eight weeks before and was still draining leads me to believe that this man had, in addition to a portal obstruction, tuberculous adenitis. We have from the history good reason to think that he had evidence of portal obstruction in the initial illness nine years previously. I further believe that he had sufficient improvement in liver function to be able to carry on fairly normally for some time thereafter. The fact that he did not use alcohol

was in his favor, and may have been responsible for his having lived so long. There are a number of questions to which we should like to know the answers. What was the cause of the repeated hematemesis? The patient had been x-rayed on three occasions in two or three different institutions, and each time he was reported to have a duodenal ulcer. On the other hand, according to my interpretation, he was suffering from a disease that is sometimes complicated by hematemesis, namely, portal cirrhosis of the liver. He had three massive hemorrhages and lived nine years. If the bleeding was from esophageal varices, it is very unusual, but I suppose it could and I believe it does happen; therefore, bleeding alone does not enable us to state whether these hematemeses always resulted from a duodenal ulcer or varices or perhaps both. I am a little inclined to believe, although I am unable to prove it, that the final hematemesis could very well have been due to bleeding from esophageal varices. If we are dealing with a man who had evidence of portal obstruction due to cirrhosis for at least nine years, esophageal varices would not be unusual. I take it that no gastrointestinal examinations were made here.

DR. MALLORY: None were made in this hospital.

DR. BAUER: If varices were looked for, they were not found, or at least they were not mentioned in any of the x-ray reports. I rather hesitate to throw out the diagnosis of duodenal ulcer.

What was the cause of the fever? A suppurative adenitis is sufficient cause for a temperature of 104°F. However, patients with cirrhosis may run a low-grade fever. The combination of the suppurative adenitis and cirrhosis of the liver would adequately account for the fever. The intercurrent infection probably served as a sufficient additional load on the liver to precipitate serious liver failure. One might explain the fever on the basis of such a combination of factors. The very fact that this man had cirrhosis for at least nine years means that we must bear in mind the possibility of a hepatoma, which may also cause fever.

There remains still another possibility, namely, tuberculous peritonitis, a complication of cirrhosis of the liver. I have interpreted the cervical adenopathy as being tuberculous in nature and therefore wonder if a hematogenous spread had not resulted in tuberculous peritonitis. If this occurred, we must also raise the possibility of miliary tuberculosis. The cause of death was obviously hematemesis in a man who was seriously ill at the time he entered the hospital. As I said be-

fore, I believe that the final hematemesis was due to bleeding from esophageal varices.

We might reconstruct this story as follows: catarrhal jaundice twenty-five years previously, followed by cirrhosis of the liver, an occasional sequela. Subsequently, an exacerbation of the tuberculous adenitis, with eventual dissemination of tubercle bacilli, resulted in tuberculous peritonitis and perhaps tuberculosis elsewhere. This added infection was responsible for further injury to the liver. The last hematemesis was responsible for his exitus. I realize that a diagnosis of tuberculous adenitis and cirrhosis of the liver, in addition to hemorrhage from either a duodenal ulcer or an esophageal varix, is adequate to account for all that this man showed, but I am rather intrigued with this other possibility, because we know that tuberculous peritonitis is one of the complications of cirrhosis of the liver.

For my final diagnosis, I shall say that this man at autopsy showed cirrhosis of the liver, tuberculous adenitis, tuberculous peritonitis, healed duodenal ulcer, possibly miliary tuberculosis and possibly hepatoma, and that he died of ruptured esophageal varices. The x-ray changes in the glenoid fossa are left unaccounted for. If my memory serves me correctly, metastases from hepatoma are not very common, especially this far removed.

DR. MALLORY: Hepatoma does metastasize to bone.

DR. BAUER: Yes; but it is not very common. This picture is consistent with Paget's disease, and I should like to account for the bone lesions on this basis. This would make my interpretation much easier.

DR. J. H. MEANS: I should like to cite a case with several points of similarity that bear on the combination of cirrhosis of the liver and hematemesis. Several years ago, there was a man, older than this one, who the service thought had the classic picture of cirrhosis of the liver, with ascites, hematemesis and so forth. We thought, of course, that he was bleeding from varices but the X-ray Department persistently refused or were unable to find any varices, which was a little disconcerting. The patient died, and it was proved that he did not have cirrhosis of the liver or varices and bled from a duodenal ulcer.

DR. BAUER: I do not see how one can say that this mistake did not occur in this case. I realize that it is rather foolish of me to assume that the hemorrhage came from esophageal varices. After all, three hospitals have stated that he had a duodenal ulcer, and it is hard to go against these reports. On the other hand, a man who has had

cirrhosis of the liver for nine years is an excellent candidate for esophageal varices

DR. WILLIAM RICHARDSON. What about the specific gravity of the abdominal fluid? It was 1.010. Would that be evidence against tuberculous peritonitis?

DR. BAUER: I think it would. On the other hand, marked ascites and slight exudation might give such a figure. That would not disturb me unduly.

DR. MALLORY. A point raised by Dr. Chester M. Jones was that the patient had just had a large hematemesis. Ascites frequently occurs after hemorrhage as the result of a sudden lowering of the serum protein. Such a mechanism might affect the specific gravity of the fluid

#### CLINICAL DIAGNOSES

Abscesses of liver, multiple.  
Cirrhosis of liver, toxic

#### DR. BAUER'S DIAGNOSES

Cirrhosis of liver  
Tuberculous adenitis  
Tuberculous peritonitis  
Duodenal ulcer, healed.  
Miliary tuberculosis?  
Hepatoma?  
Ruptured esophageal varices

#### ANATOMICAL DIAGNOSES

Liver abscesses, multiple.  
Tuberculous cervical adenitis and peritonitis  
Miliary tuberculosis, generalized  
Cholecystitis, chronic.  
Cholelithiasis.  
Choledocholithiasis  
Esophageal varices (no thrombosis of portal and splenic veins)  
Ascites

#### PATHOLOGICAL DISCUSSION

DR. MALLORY. Several of Dr. Bauer's predictions are correct, but the bases on which he founded his reasoning are almost entirely incorrect as judged from the results of autopsy. The patient had a generalized tuberculosis, with frankly caseous cervical lymph nodes, with an extremely extensive tuberculous peritonitis and with miliary tubercles throughout the spleen and liver. There was no cirrhosis. There was no mechanical portal obstruction. I did not believe the intern, and I personally dissected out the portal vein. There were esophageal varices, unexplained, and no trace of any ulcer in the duodenum or any scars. There were two very large liver abscesses, one 3 and

one 5 cm. in diameter. There were stones in the gall bladder and the common duct, and there was a cholangitis. I believe that the liver abscesses were pyogenic in character. On smear, the pus contained many diphtheroid bacilli; no tubercle bacilli were found. The explanation for the varices in the absence of portal obstruction, I cannot offer. I have seen it four or five times, and it does occur.

One can only guess, it seems to me, in retrospect about the ascites nine years before entry. Tuberculous peritonitis at that time with spontaneous recovery is the best guess. One certainly does see spontaneous recovery from tuberculous peritonitis, and I cannot believe that he could have had a portal obstruction that left no trace.

DR. WILLIAM B. BREED. What was the size of the liver and spleen?

DR. MALLORY. The spleen weighed 600 gm.; the liver was normal in size, weighing 1500 gm.

A PHYSICIAN: What were the other cases of varices and no portal obstruction?

DR. MALLORY. They occurred chiefly in elderly men. I remember only one specifically, a man in the late seventies or early eighties, with massive hematemesis from esophageal varices but no portal obstruction.

DR. BAUER. Do you conclude that he did not have duodenal ulcer and that he had always bled from varices?

DR. MALLORY. It is the only conclusion I can reach.

DR. RICHARD H. SWEET. What did the clinicians have in mind when they gave Thorotrast—liver abscess?

DR. MALLORY. It sounds as if they did.

DR. DAVENPORT. It was given at the suggestion of Dr. Jones, who believed that the prognosis was hopeless, and that there was no danger in giving it. He hoped to outline an abscess or hepatoma.

A PHYSICIAN: What was the clinical diagnosis?

DR. DAVENPORT. Cirrhosis of the liver, with presumable liver abscess because of the fever. The lymph nodes we considered tuberculous—I do not believe we had enough emphasis on the possibility of tuberculous peritonitis.

#### CASE 27442

#### PRESENTATION OF CASE

A forty-three year old Negro stableman was admitted to the hospital because of severe pain in his chest for about twelve hours.

The patient had been well until about three months before entry, when he developed a cough that was productive of blood stained sputum. The

cough was painless, and was always more severe at night, after he had gone to bed. After a month, the sputum ceased to be blood tinged, and remained yellow and purulent.

The patient was free from other symptoms until the night before entry, when, while sitting in front of his barn, he was attacked quite suddenly by pain in the left side of his chest. The pain was sharp, severe, and so aggravated by breathing that he dared scarcely to inhale. He took some whiskey to ease the pain, and went to bed. He slept for a while, only to awake with a similar pain in the right chest. Later in the night, he sweated profusely and had a frank, shaking chill. The next morning, he entered the hospital in considerable distress, complaining of pain on both sides of the chest.

While the patient was a child, both his parents had died of tuberculosis. He had followed race horses all his life, living in or near stables. Twenty years before entry, he had received a large knife wound in the right upper arm. Syphilis was denied, but he had received arm and hip "shots" for a "cold" the winter before entry.

In the three months preceding admission, he had lost 15 pounds.

On examination the patient appeared well developed and well nourished despite some recent weight loss. The expansion of his chest was limited bilaterally. There was occasional coughing, brassy in character. Loud friction rubs were heard over the lower half of each lung field. Breath sounds were definitely diminished in the left chest, although tactile and vocal fremitus were normal, and there were no changes to percussion. The heart did not seem enlarged. The blood pressure was 140 systolic, 90 diastolic.

The temperature was 101°F., the pulse 104, and the respirations 28.

The blood showed a red-cell count of 3,190,000, with 11 gm. hemoglobin. The white-cell count was 14,750 per cu. mm., with 85 per cent polymorphonuclears. The blood Hinton and Wassermann reactions were both positive. Repeated blood cultures were negative. The urine was not remarkable. Numerous examinations of the sputum failed to reveal tubercle bacilli or fungi. On one occasion, a Type 3 pneumococcus was isolated.

A roentgenogram of the chest showed slight enlargement of the heart, affecting especially the left ventricle. At the junction of the ascending portion and arch of the aorta, there was a multilobular dilatation, which seemed to compress slightly the left main bronchus. There was mottled consolidation in the left lower lobe of the lung, in the lower half of the right upper lobe

and in the right lower lobe. The left upper lobe seemed emphysematous. There was no free pleural fluid. The patient was given sulfathiazole and later switched to sulfapyridine. The temperature continued to fluctuate daily from 99 to 102 or 103°F., but the pain disappeared and the cough improved. Early in the fourth week of his hospital stay, severe pleuritic pain in the left chest reappeared for a few days. Re-examination showed dullness in the left axilla and at the left base, with diminished breath sounds. A patch of tubular breathing was present at the left base anteriorly. After this, the patient was given potassium iodide in daily doses, and weekly injections of bismuth.

Another roentgenogram of the chest, taken a month after the earlier film, showed several cavities in the left lower lobe, with fluid levels. The area of infraclavicular consolidation had increased and seemed to include a small cavity.

Bronchoscopy was performed late in the sixth hospital week. The left main bronchus was narrowed and edematous at the orifice, with a considerable amount of thick, gelatinous mucoid secretion. The bronchus to the left lower lobe was narrowed, and contained similar mucoid secretion. A biopsy of the mucosa of the left main bronchus showed no diagnostic abnormality. A roentgenogram of the skull showed no evidence of intracranial metastatic lesions.

On the fifty-ninth hospital day, without premonition, the patient suddenly had a massive hemoptysis, spraying blood all over the room. His mouth and nose filled with frothy clot, and he became pulseless and expired.

#### DIFFERENTIAL DIAGNOSIS

DR. EDWARD F. BLAND: This was a dramatically fatal illness, so far as I can judge from the record, extending over a period of only five months. In exploring the various possibilities, I think we must keep in mind what to me seem to be the essential features of this illness, namely, a progressive subacute pneumonic process in both lungs leading to abscess formation, cavitation and terminal erosion of a large arterial vessel. The diagnostic problem concerns the specific etiologic agent involved, and I hope for considerable help from the X-ray Department on this point. There are two specific questions I should like to ask the roentgenologist. I am bothered by the term "multilobular dilatation" of the aorta. I should like to clear that point up, because most syphilitic alterations in the aorta result in either a diffuse dilatation or a saccular aneurysm. Secondly, does Dr. Lingley find any evidence in the films to indicate osteomyelitis of the thoracic cage?

DR JAMES R LINGLEY There are a number of films, taken over an interval of five weeks. The first film shows widening of the superior mediastinum, which was due to enlargement of the aorta. In the lateral view, one can see marked anterior bulging of the ascending portion and also dilatation of the upper part of the descending portion of the aorta, producing much compression and narrowing of the left main bronchus. The ascending aorta is definitely dilated in a fusiform manner and also shows localized bulges—hence the term ‘multilobular dilatation’. The lesion in the descending aorta is a sacular aneurysm. The process in the lungs at the first observation consisted of a bilateral mottling most evident on the left side at the base and on the right in the midchest and upper chest. During the period of observation, this changed considerably. The process at the left base increased markedly over a period of five days, while the process in the right upper diminished. The patient then developed a new process in the left upper lung followed at a later period by cavity formation both here and in the area of consolidation at the left base. The thoracic cage appears normal.

DR BLAND Now that I have seen the films, I am willing to accept the x-ray interpretation of multiple aneurysmal dilatations of the aorta. Of more importance are the pulmonary lesions. We are dealing with a Negro, and the first thing that comes to my mind is “galloping consumption”. There is, however, some very good bacteriologic evidence against it, so much so that I doubt if this patient actually had tuberculosis. In the first place, with an acid fast bronchopneumonic process of this extent, it is usually relatively easy to demonstrate bacilli in the sputum. I am sure that a very thorough search was made for these organisms, and I am reasonably certain, since this man was on the ward here, that the study included repeated examinations of the gastric contents.

DR TRACY B MALLORY It did.

DR BLAND Furthermore, it is probably true that the material was not only examined but also injected into suitable animals.

DR MALLORY Guinea pig inoculation was done, but no report was available at the time of the patient's death.

DR BLAND Nevertheless, I think the strong, but of evidence, and in fact the only evidence, against tuberculosis is that the organism in this very active process was not demonstrated. Secondly, the lesions here are predominantly at the base of the lungs, that is somewhat against tuberculosis. Finally, I think there are two clues in the clinical record indicating that those in charge

of the patient discarded the idea of tuberculosis—they treated him with iodides—consequently, they must have had some other etiologic factor in mind at that point, also, the patient was bronchoscoped. Ordinarily, in the presence of an active tuberculous process, one does not administer iodides nor does one like to bronchoscope the patient, unless there are very special indications for the latter procedure. Adding up this evidence, then, I shall have to discard tuberculosis.

Next, in searching for other possibilities, I am rather impressed by the fact that three times in the record we are told that this man was closely associated with horses and stables. The Pathology Department in these exercises does not usually stress such possible clues so persistently, therefore, I suppose I should pay special attention to them. Following this lead, the first thing to think of is mycotic infection of the lung. By that term, one means a variety of infections in the lung due to fungi, molds and yeasts. The commonest fungous infection among people who deal with animals and stables is actinomycosis. When the lung is involved, there are often lesions of the skin or subcutaneous structures, not infrequently resulting in draining sinuses. We have no evidence of such lesions here, and Dr Lingley has pointed out that there was no rib involvement. On the other hand, approximately 15 per cent of actinomycosis in human beings may be limited to the lungs. In others, it may be limited to the gastrointestinal tract. It is of some interest that most people believe infection takes place not by direct contact with infected animals or by eating the meat of such animals, but rather from the handling of hay and grain. I hope Dr King will correct me if I have made any misstatements in this connection, for I naturally do not feel so much at ease in dealing with the lungs as with the heart. In considering actinomycosis as possibly responsible, I am a little bothered that the ribs were uninvolved, and that there were no draining sinuses. I am also further disturbed by the fact that they were not able to demonstrate the organism either in the sputum or in the material that came from the bronchoscopic examination, but this does not exclude actinomycosis. On the other hand, the somewhat chronic course with hemoptysis and cavity formation is a part of the general clinical picture of mycotic infection of the lung, especially actinomycosis. The mucoid character of the sputum is fairly characteristic. Another point somewhat against it is that the patient presumably did not respond to chemotherapy. However, I do not believe we have had enough experience with chemotherapy in mycotic infections to assess this

evidence one way or the other. There are several reports pointing out that some patients do respond favorably. We also do not know how much chemotherapy was actually given. Perhaps there was some special reason for switching from sulfathiazole to sulfapyridine and then omitting it entirely. Perhaps they were never able to get the blood level high enough, but we can only speculate about that. I must say that since acid-fast bacilli could not be found I view with favor the possibility of actinomycosis.

In searching for other possibilities in a person associated with stables, one thinks of tetanus. There is no place here for tetanus that I can see. Then we think of anthrax. There are reported cases of pulmonary anthrax, a rapidly fatal disease; the patient usually dies in a few hours or a day or two and actually often before physical signs are demonstrable in the lungs. Finally, there is the possibility of glanders in the lung; but that would be a little fanciful here.

Another condition one must think of as a cause of subacute or chronic pulmonary consolidation is Friedländer's pneumonia. About 3 per cent of pneumonias are due to the gram-negative encapsulated Friedländer's bacillus. It is usually acute, lasting something like eight to fourteen days; but now and then it may be a more chronic process such as this patient showed, and it is often associated with hemoptysis, consolidation and multiple cavitation of the lung—the result of a non-putrid pulmonary necrosis. The sputum is often mucoid, but I am also disturbed here by the fact that the organism could not be demonstrated. There is no specific statement in the record concerning Friedländer's bacillus; it would have been mentioned if found. Therefore, I think that this was not Friedländer's pneumonia.

Is there any possibility of neoplastic disease, either primary or secondary, carcinoma or lymphoma? I do not believe so. The x-ray report does not suggest it. The bronchoscopic examination simply shows narrowing of the left main bronchus, probably from external pressure of the dilated aorta, possibly in part from chronic inflammatory swelling inside the air passage itself. Biopsy of this area failed to reveal evidence of cancer.

We know that the patient had syphilis. Can we bring syphilis into the picture otherwise than by its probable involvement of the aorta? Syphilis of the lung itself is rare. Cases of gumma have been described, and have been seen here in this hospital. This patient was treated with iodides and bismuth, not, I suppose, because anyone thought there was syphilitic involvement of the lung but rather because the patient had positive

serologic findings and a large aorta. Rarely, syphilis may involve the pulmonary artery, usually with aneurysmal dilatation, or very occasionally as a form of endarteritis of the smaller radicles but I see no evidence for suspecting such a diagnosis here.

Did the patient inhale a foreign body caused obstruction, secondary infection and bronchiectasis? There is no evidence to suggest from the history or subsequent course.

I keep asking myself whether we are trying to make this case too complicated. Was this, after all, simply bronchiectasis of the lung present long time and more or less latent until the terminal infection? There were no symptoms in the past to suggest such a process. They are always necessary. Perhaps bronchiectasis under pressure by the aneurysm on the left main bronchus, with secondary infection behind it that spread to the other lung, is a possibility. I do not see how we can say yes or no. I am inclined to think that there was some specific infectious cause of this lung other than simple mechanical obstruction of the bronchus and trapped infection.

After exploring these various etiologic possibilities, I can briefly summarize by saying that I am back to where I started. The evident diagnosis is that of a bilateral pulmonary infection with multiple abscess formation and cavitation of undetermined etiology, in addition to a question of actinomycosis. The patient undoubtedly had syphilis, with aneurysmal dilatation of the aorta. Then there was the terminal pulmonary hemorrhage. Obviously, a large vessel was eroded. Was it the aorta? Was it rupture from pressure within, was it aggravated by weakening of the wall of the vessel from without, or was it simply an erosion of a large pulmonary vessel? I do not know how we can decide. My impression is that rupture of the aorta leads to rather instantaneous death. In this case, those who saw the patient had time to make a few observations. They did not say whether the blood was bright red or dark red, suggesting it might have been from the aorta in the first event or from the pulmonary artery in the second. I do not know how we can decide where it came from, but certainly it was from a large arterial vessel.

DR. DONALD S. KING: We saw this patient several times in the Thoracic Clinic. At first agreed with the student who took the history that the diagnosis was pulmonary tuberculosis, but we were baffled by the repeated negative sputum examinations, and began to look for other possible etiologic factors. Because of his association with horses, we thought, as Dr. Bland did, of ac-

mycosis, but could never prove it. In speaking of actinomycosis, it might be well to note that the disease may develop in city dwellers who have had no contact with animals. We recently had such a case in a young female stenographer. In the present case, we thought also of Friedlander's infection, but could not find the organism. We then got interested in the possibility of pulmonary syphilis and agreed with the recommendation that antisyphilitic treatment be tried.

Dr Bland raised the question of bronchoscopy in cases of pulmonary tuberculosis, and I should perhaps say that, at times, even with acute pulmonary tuberculosis, bronchoscopy is indicated. We are coming to recognize bronchial tuberculosis as a fairly common complication. An acute bronchial obstruction from tuberculous infection may have to be relieved by the bronchoscopic procedure. If proper drainage can be established, fever and other untoward symptoms may be promptly relieved. In the present case, if there was definite evidence of obstruction to the left lower lobe bronchus, bronchoscopy was justified, even though there was the possibility of the diagnosis of tuberculosis.

Dr Lingley, if you saw this x-ray film and did not know the story, would the diagnosis be evident?

Dr LINGLEY. The x-ray appearance would fit actinomycosis very well, in spite of the lack of rib destruction. It is unusual for tuberculosis to be at the base predominantly and for the consolidation to fluctuate so much. I do not know of any positive method of making a diagnosis of syphilis of the lung, although various criteria have been suggested. I think actinomycosis is as good as anything.

Dr KING. Would you have guessed that if you had seen the film?

Dr LINGLEY. Chronic pulmonary infection with cavitation is as far as I can go on the films alone.

Dr KING. I know the diagnosis now, but as I see the films from here it seems that we should have made the diagnosis from them. The fact that the process was predominantly basal does not rule out tuberculosis. There also was bilateral apical infection.

Dr BLAND. What was the clinical diagnosis on the death report?

Dr MALLORY. Chronic pulmonary suppuration, tertiary syphilis, with aortic aneurysm and terminal rupture into a bronchus.

Dr BLAND. Where did you think the terminal hemorrhage came from?

Dr KING. I know the autopsy findings, but I think that the service made the correct diagnosis.

#### CLINICAL DIAGNOSES

Chronic pulmonary suppuration  
Tertiary syphilis, with aortic aneurysm and terminal rupture into a bronchus

#### DR BLAND'S DIAGNOSES

Chronic pulmonary infection of undetermined etiology (actinomycosis?)  
Multiple pulmonary abscesses  
Tertiary syphilis  
Aortic aneurysms  
Terminal hemorrhage

#### ANATOMICAL DIAGNOSES

Syphilitic aortic aneurysms (three), with rupture of one into the left lower bronchus  
Hemorrhage into lung  
Syphilitic aortitis  
Compression of left bronchus by aortic aneurysm  
Pulmonary tuberculosis, bilateral, with cavitation  
Secondary erosion of vertebral bodies by aneurysmal dilatations

#### PATHOLOGICAL DISCUSSION

Dr MALLORY. The autopsy showed marked dilatation of the aorta, with multiple aneurysms, two of which were definitely saccular, the third being a more diffuse dilatation. The larger aneurysms were found in the ascending portion, and the smallest aneurysm was just beyond the arch in the descending portion. It had become adherent to the left primary bronchus and had ruptured into it terminally; death was due to the inhalation of tremendous amounts of blood throughout the bronchial tree and even into some of the alveoli. The patient essentially drowned in his own blood rather than dying of hemorrhage. The pulmonary picture was somewhat confused from the gross point of view by the massive inspiration of blood, but many areas of consolidation were found scattered throughout all lobes of the lung, some of which showed varying degrees of caseous softening and some frank cavitation. On gross examination, it was not recognized as tuberculosis, but on microscopic examination it was perfectly obvious. Eventually, the guinea pig that had been inoculated with the gastric contents was found to show tuberculosis. The heart itself was not involved in the aortic process. The lesion was too high to affect either the aortic valve or the coronary ostia.

## AMERICAN COLLEGE OF SURGEONS

FROM November 3 through November 7, the surgeons of Metropolitan Boston will be hosts to the clinical congress of the American College of Surgeons, with headquarters at the Hotel Statler. These annual meetings are among the greatest and most effective educational gatherings that are held by any branch of the profession. The surgeons of the large local hospitals will demonstrate their methods and ability, and many distinguished visitors will give addresses or take part in the discussions. Among the guest speakers will be Dr. Evarts A. Graham, of St. Louis, the president of the college, and Dr. W. Edward Gallie, of Toronto, the president-elect. From abroad will come Rear-Admiral Gordon Gordon-Taylor, of London, and Professors Pablo Luis Mirizzi, of

Cordoba, Argentina, and Moacyr Eyck Alvaro, of Sao Paulo, Brazil.

In addition to surgical clinics, round-table conferences and scientific meetings in the daytime, the Presidential Meeting and Convocation is scheduled for Monday evening, and formal scientific lectures for the following three evenings. On Friday evening, the Boston Surgical Society will hold a special meeting, at which Dr. Allen O. Whipple, of New York City, will be awarded the Bigelow Medal.

Matters pertaining to hospital standardization will be discussed at meetings held at the Copley-Plaza. These gatherings should be of interest to physicians, hospital executives, nurses and laymen, and particular emphasis will be placed on proper systems for the making-out and filing of hospital records.

Admission to the clinics and surgical round-table conferences will be by ticket only, to prevent overcrowding. For members or junior candidates of the College, the registration fee is \$5.00, payable at the registration desk at the Hotel Statler; candidates accepted by the College for induction at this meeting may register without charge. For nonfellows attending the congress as invited guests of the College, the registration fee is \$10.00. No fee is involved for attendance at the meetings concerned with hospital standardization, but all who plan to be present should register at the desk at the Copley-Plaza.

## NUTRITION AND DEFENSE

THE old adage, "An army travels on its stomach," might well be changed to "A nation travels on its stomach." There was a time when the fighting of wars did not greatly disturb the activities of much of the populace. But times have changed. World War II gives ample demonstration that efficiency and morale on the home front are as essential for winning wars as fighting on the battlefield. Warfare has so changed that millions of workers behind the lines are required for the continued delivery of supplies and mechanical equipment to the fighters. There is a

considerable medical literature to attest that malnutrition in its various forms impairs this physical efficiency and morale so essential to victory

A recent study by Williams and Mason\* adds convincing evidence for this contention. These investigators placed a number of healthy adults on a diet adequate in all respects but with a thiamin content of only 0.40 to 0.45 mg daily. They point out that this approximates the thiamin content found by Stebeling and Phipard in the diets of many American families. After four to six months, in addition to other manifestations, these subjects became depressed, irritable, quirkish, fearful, inefficient in work because of generalized fatigue, inattentive to details, uncertain of memory and lacking in manual dexterity. These symptoms slowly disappeared when additional thiamin was added to the diet. This is a convincing demonstration of the necessity of thiamin for emotional stability. Indeed, thiamin has been referred to in the lay press as the "morale vitamin," and people in the occupied countries are said to be more easily kept in a subjugated state because the low thiamin content of their diets has robbed them of their will to fight.

Thiamin, however, is only one of the many factors that may be absent in a poor diet. At the National Nutrition Conference for Defense, held in Washington this May at President Roosevelt's request, the frequent inadequacy of the American diet was frankly discussed. Specific recommendations for improving the nutrition of the people were made to the President. The exigencies of the hour necessitate that the advantages to accrue from the application of nutritional principles to defense efforts begin as soon as possible. Aside from these immediate objectives, the nutritional program now getting under way in this country has far-reaching implications and may materially influence the pattern of morbidity in the generations to come. At the conference, all physicians were urged to take an active interest in these nutritional problems and to assume leadership in the field. The progress report in this

issue of the *Journal* reviews material with which every physician should be familiar.

## MEDICAL EPONYM

### KRONIG'S ISTHMUS

Dr Georg Kronig (1856-1911), docent in the University of Berlin, published his paper "Zur Topographie der Lungenspitzen und ihrer Percussion (On the Topography and Percussion of the Lung Apices)" in the *Berliner klinische Wochenschrift* (26: 809-812, 1889). A portion of the translation follows:

The examination of a patient who had been referred to me was the beginning of a series of determinations of the borders of the lung apices, as well as the lung margins which I briefly report here. After I had determined the anterior supraclavicular margin of the lung in the usual fashion, that is by gentle percussion, I proceeded, still percussing very lightly to the posterior aspect and thereby obtained the following results. On the right side, as on the left, there appeared a line that extended medially in a wide arch, with its convexity directed inward, and approached to within a centimeter of the midline on the left at the level of a line between the second and third thoracic spines, on the right at the level of the fourth thoracic spine. In this case, the right apex was diseased while the left showed a normal condition. Inasmuch as I had obviously been successful in determining not only the height of the lung apices but also their breadth, I tried to determine similarly the lateral margin. The determination of the posterior lateral border is easy in many cases, especially in thin persons, but is frequently difficult in powerfully built, extremely muscular, or fat persons. The lateral border, which I have outlined on the anterior surface is extremely trustworthy. It runs from about the middle of the anterior margin of the trapezius muscle, curves down sharply, cuts the clavicle at about the line between its middle and outer third, and then courses outward diagonally to the axilla. From the configuration of these normal clinical margins, it will now be possible, without great difficulty, to hypothesize the necessary shift that will occur when there are pathologic changes in the lung apices. Diseases that reduce the air content will shift the medial border outward and the lateral border inward.

### SECTION OF OBSTETRICS AND GYNECOLOGY†

#### AIR ENBOLUS FOLLOWING AN ATTEMPT AT CRIMINAL ABORTION

As in so many cases that the medical examiner sees, no record of the past history or physical ex-

\*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters should be addressed to Dr Raymond S. Titus, Secretary, 340 Dartmouth Street, Boston.

\*Williams R O and Mason H L. Further observations on reduced thiamine (vitamin B<sub>1</sub>) deficiency and thiamine requirement of man. *Proc Soc Exp Biol Med* 1941; 48: 433-435.

amination was available for the following case. According to the meager history obtained, the patient was single, twenty-two years old and about eighteen weeks pregnant. She went to a female abortionist, who attempted to bring about an abortion by the use of a large bulb syringe. The patient died almost immediately. Autopsy revealed air embolus in the heart and in the lungs.

*Comment.* This case is reported solely because of the rarity of such a cause of death, proved by autopsy. Each year since the Maternal Mortality Study was begun, 25 to 30 fatal criminal or self-induced abortions have been reported in Massachusetts. That the above-mentioned abortion was performed in such a manner by a female abortionist probably relieves the medical profession of any responsibility. The danger of this method of abortion must be so well known to the profession that it is doubtful whether any registered physician would attempt it.

## DEATH

MASON—ATHERTON P. MASON, M.D., of Fitchburg, died October 20. He was in his eighty-sixth year.

A native of Fitchburg, Dr. Mason received his degree from Harvard Medical School in 1882. He was a former president of the Worcester North District Medical Society, and was a member of the Massachusetts Medical Society and the American Medical Association.

He is survived by a daughter.

## NOTICES

### JEWISH MEMORIAL HOSPITAL

A diagnostic therapeutic conference will be held at the Jewish Memorial Hospital on Thursday, November 6, at 11 a.m. Dr. Valy Menkin will discuss "Inflammation."

Interested physicians and medical students are cordially invited to attend.

### MASSACHUSETTS PSYCHIATRIC SOCIETY

The annual meeting of the Massachusetts Psychiatric Society, with the election of officers, will be held at the University Club, Boston, on Friday, November 7, at 6:30 p.m. The guest speaker will be Dr. Winifred Cullis, professor emeritus of physiology, University of London, whose topic will be "London Hospitals in Wartime."

### NEW ENGLAND OTO-LARYNGOLOGICAL SOCIETY

The fall meeting of the New England Oto-Laryngological Society will be held at the Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston, on Wednesday, November 19, at 4:30 p.m. The clinical meeting will be followed by a buffet supper.

### NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children

will be held on Thursday, November 6, at 7:15 p.m. in the classroom in the nurses' residence. A motion picture, "Studies in Human Fertility," will be shown. Dr. Mary I. Tompkins will be chairman.

### AMERICAN ORTHOPSYCHIATRIC ASSOCIATION

The nineteenth annual meeting of the American Orthopsychiatric Association will be held at the Hotel Statler, Detroit, Michigan, on February 19, 20 and 21.

A registration fee will be charged for nonmembers. Further information may be obtained from Dr. Helen P. Langner, chairman, Publicity Committee, Vassar College, Poughkeepsie, New York.

### CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS, UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

CLINIC	DATE	CLINIC CONSULTANT
Salem	November 3	Paul W. Hugenberger
Lowell	November 7	Albert H. Brewster

## SYMPOSIUM ON HORMONES

### COMPLICATIONS OF THYROID-SUBSTITUTION THERAPY\*

WILLIAM T. SALTER, M.D.†

BOSTON

Preparations of endocrine glands in the form of crude extracts or purified synthetic active principles may be classified from a pharmacological viewpoint as drugs of animal origin. Whereas most drugs are substances foreign to the body, the hormones are normally present and active in tissues where they have a physiological function. For this reason there is some tendency to place hormones in a different category from drugs. There is no valid reason for this, however, and indeed the older endocrine preparations have unobtrusively broken down this arbitrary distinction. For example epinephrine is much more frequently viewed as a powerful sympathomimetic drug than as the hormone of the adrenal medulla.

The fact that the drugs of endocrine origin do have a physiological function has aided considerably in the elucidation of their mechanisms of action. A drug foreign to the body can only be studied with respect to its positive effects after administration. Observations on the response to a deficiency or an excess of a hormone can be made both in the clinic and in the laboratory. With this dual investigative method, much has been learned concerning the mechanisms of action of the hormones. Despite the extensive physiological and pharmacological evidence available, the endocrine preparations are probably more often misused in therapy than any other group of drugs. Extravagant claims are often made for their efficacy, and they are widely employed in conditions entirely unrelated to hormonal deficiency. Routes of administration are frequently used which preclude the possibility of obtaining pharmacodynamic action. Rational therapeutic employment of drugs of endocrine origin clearly depends on a thorough knowledge of their chemistry, and of their physiological and pharmacological actions.

Goodman and Gilman<sup>1</sup>

**A**LTHOUGH thyroid substitution therapy is one of the best known and most reliable types of endocrine treatment, a number of features concerning it are apt to be overlooked in the course

of a busy practice. These involve not only certain therapeutic hazards that attend the use of this medication, but also neglected opportunities for permanent good. The thyroid hormone has two main effects: first, that of growth and maturation and, secondly, that of the release of energy. The physician must take advantage of these properties, while avoiding their undesirable features. In this respect, the wise use of thyroid medication requires a considerable acquaintance with the art of medicine.

#### TYPE OF THERAPY

For most purposes, desiccated thyroid—thyroid *U S P*—is to be preferred to any other type of thyroid preparation, because in general it is cheaper and because its assimilation is better assured. Thyroxin crystals are so insoluble that they may pass through the gastrointestinal tract with little if any absorption, and at best the degree of absorption is frequently unreliable, even when the crystals are administered in solution. Therefore, thyroid *U S P* should ordinarily be given only by the parenteral route, either when difficulty in absorption by the intestine is anticipated or when, for scientific or other reasons, it is desirable to know definitely how much of the drug reaches the circulation. Such conditions might involve massive edema of the intestine, ulcerative lesions or even steatorrhea. Likewise, very rarely, protein sensitivity may lead to allergic symptoms like urticaria, which preclude the use of glandular preparations. If thyroxin is given, it should be dissolved in dilute alkali (N/100) and further diluted (N/1000) just before injection. Ordinarily, however, both for the treatment of frank myxedema and for other therapeutic purposes, one should employ desiccated thyroid, usually in tablets containing 1 gr. (60 mg.) of the material, commonly given twice daily.

\*This and the three subsequent papers were presented as part of a symposium at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1941.

From the Thorne Medical Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School, Boston.

†Formerly assistant professor of medicine, Harvard Medical School, and associate physician, Thorne Medical Laboratory, and junior visiting physician, Boston City Hospital.

## THERAPEUTIC HAZARDS

In the treatment of myxedema, care must be exercised, particularly in older people, lest the reserve of certain organs be overtaxed. These include especially the heart and the adrenal cortex. The danger of precipitating acute dilatation of the heart, with left-sided failure, acute pulmonary edema, anginal seizures and even coronary thrombosis, has often been commented on,<sup>2</sup> and need not be amplified further. Less well known is the precipitation of acute shock, Addisonian in type, in a disorder that Means et al.<sup>3</sup> have classified as "hypothyroidism masquerading as myxedema." Many endocrinologists would consider this type an early stage of Simmonds's cachexia, in which thyroid lack had become more prominent than disturbances in the other endocrines. Such cases, however, can be verified properly if special attention is paid to points in the history that suggest hypogonadism and the symptoms and signs of Addison's disease. The presumptive diagnosis can be verified by the appropriate use of insulin-tolerance and glucose-tolerance tests.<sup>4</sup> Obviously, such a case must be treated with thyroid only under hospital control and with extreme care.

The dosage tolerated by a patient with classic myxedema varies with the patient's age. Many young patients (under twenty years of age) tolerate without difficulty as much as 4 gr. a day of thyroid *U. S. P.*, although this dosage is not to be recommended routinely. On the third to the fifth day of treatment, they may experience a certain amount of mild fever and muscle pain of minor character; otherwise, little discomfort results. Under such dosage, the patient's metabolism usually reaches -10 per cent in two weeks, and if the dosage is continued, it slowly rises to normal in a month after the beginning of therapy. Older people must be treated more cautiously, even in the absence of definite heart disease. Thyroid is in itself, of course, a diuretic, and at all levels of metabolism will produce a certain degree of diuresis unless heart failure is precipitated, when the diuresis may be masked by increasing edema due to heart disturbance.

As pointed out by Goodman and Gilman<sup>5</sup> and others,  $\frac{1}{2}$  gr. a day will, in the course of a month, bring the metabolism up to -35 per cent, 1 gr. to -25 per cent, 2 gr. to -15 per cent, and 3 gr. to -10 per cent. Equivalent dosage for thyroxin has been given by Thompson and his associates.<sup>6</sup> With this approximate scheme in mind, one may start in with  $\frac{1}{2}$  gr. a day for ten days, and slowly elevate the dosage each week as required. Usually, not more than 2 gr. (120 mg.) daily suffices.

Some patients must be content with a subnor-

mal level because their hearts do not tolerate a normal metabolic rate without the onset of cardiac failure or of angina pectoris. In general, the basal metabolic rate may be as low as -20 per cent before the layman can detect a difference in the patient's appearance or personality. Indeed, the patient sometimes prefers this level because he finds life far less worrisome.

In cretins, adjustment of the dose is particularly precarious because there seems to be a rather narrow margin of safety between an inadequate dose and one that produces violent mental symptoms.<sup>7</sup> Indeed, in untreated cretins over fifteen years of age, there is a prevailing sentiment that treatment may often be worse than useless because it merely makes the patient unhappy and intolerable to other members of society. In juvenile myxedema, this limitation is less disturbing, and for the sake of the general development and growth of such young people, it is desirable to run them constantly with a somewhat elevated metabolism. In fact, it is surprising how content very young people can be for long periods with a basal metabolic rate that is close to +20 per cent. Accordingly, children often well tolerate doses ordinarily given to adults.\* On the contrary, an old person frequently complains bitterly at a level of +5 per cent.

If dosage is pushed too high in women in the childbearing age, scanty or irregular menstruation may result. On the other hand, thyroid therapy in mild myxedema may correct menorrhagia and metrorrhagia; and in profound myxedema, minimal thyroid therapy may initiate regular menstrual periods that have been stopped for some years because of thyroid lack.<sup>9</sup> One thus sees a reversal of the effect of thyroid on menstruation, that is, no periods at a basal metabolic rate of -45 per cent, menorrhagia at -20 per cent, oligomenorrhea at +15 per cent and, possibly, no periods at +50 per cent.

Even when too little thyroid secretion is present, as in myxedema, the patient may complain of nervousness, and occasionally hyperthyroidism may be suspected. This paradoxical nervousness or irritability of the hypothyroid patient may be a frustration complex analogous to that shown by older men engaged in mass production who are no longer able to maintain the speed of the assembly line. These myxedematous patients are

\*Means<sup>3</sup> has recommended the following dosage of thyroid *U. S. P.* in the treatment of cretins:

AGE	DAILY DOSAGE
2 to 4 mo.	6 mg. (1/10 gr.)
4 to 8 mo.	12 mg. (1/5 gr.)
8 to 12 mo.	18 mg. (3/10 gr.)
12 to 24 mo.	24 to 45 mg. (2/5 to 3/4 gr.)
2 to 4 yr.	30 to 90 mg. (1/2 to 1 1/2 gr.)
4 to 12 yr.	60 to 180 mg. (1 to 3 gr.)

usually content until their neighbors begin to push them, when they become harassed and irritable. With moderate thyroid dosage, they live faster and can maintain the pace of modern life. On the other hand, excessive overdosage may lead to violent maniacal attacks, accompanied by a flight of ideas and even incoherent bawling, with intermittent echolalia, babbling and other psychic phenomena. In general, these attacks are likelier to be precipitated by rapid elevation of the basal metabolic rate than by slow elevation. Of course, myxedematous patients are more sensitive to high doses of thyroid than persons whose glands are normal.

Other bodily functions may be accentuated unpleasantly by overdosage of thyroid. Among these abnormalities are diarrhea produced by increased thyroid activity, excessive sweating, palpitation and restlessness to the point of apprehension. Occasionally, particularly in older people, auricular fibrillation may be precipitated by the use of too much thyroid, and normal cardiac rhythm may be resumed when this medication is stopped. This phenomenon is not infrequently encountered in weight reduction, when an overenthusiastic patient "doubles the dose." In the absence of frank circulatory or arteriosclerotic disease, and in the presence of a normal thyroid gland, it is probably rare to see very alarming symptoms until the dose exceeds 2 gr. (120 mg.) a day. In general, of course, the same rule holds for thyroid as for many other drugs, namely, that the law of diminishing returns applies. If the patient is truly hypothyroid, a relatively small dose will produce a marked effect on the metabolic turnover, whereas if the patient is suffering from reduced metabolism due to some other cause, rather large doses may be required to produce any considerable effect on the metabolic rate. Indeed, some clinicians go so far as to say that there is little point in giving over 3 gr. (180 mg.) daily.

This therapeutic test may be applied in cases of nephrosis and of hypogonadism (hypopituitarism) or in cases of so called "substandard" (but normal) basal metabolic rate. This last group is particularly interesting because it comprises that end of the distribution of the healthy population whose basal metabolism under normal conditions happens to lie between -15 and -25 per cent. Such cases are not infrequently branded as hypothyroid on the basis of the metabolic rate determination, and treated unnecessarily. Indeed, they may erroneously be called "myxedema," when actually that term should be reserved for the characteristic clinical syndrome recognizable at the bedside. In case of doubt, chemical determination

of the plasma protein bound iodine<sup>23</sup> is a highly reliable confirmatory test.

In the minor degrees of true hypothyroidism, however, the patient may often be benefited symptomatically by thyroid, and the experienced practitioner is justified in trying the therapeutic effect in certain cases of borderline endocrine imbalance in which mild stigmas of thyroid underfunction seem to be prominent. This is true even though the basal metabolic rate lies within normal limits. Occasionally, although somewhat uncommonly, doses as high as 5 gr. a day may be necessary in young people. Farquharson and Squires<sup>10</sup> have pointed out, however, that when medication is stopped in such patients the basal metabolic rate may fall abruptly to markedly subnormal levels, and that it returns to normal only gradually, even when high calorie diets are supplied.

In other endocrine deficiencies, the use of thyroid may upset the endocrine balance disadvantageously. For example, mild diabetes mellitus may be aggravated,<sup>11</sup> or mild tetany may be enhanced. On the contrary, it is well substantiated that in lack of pituitary or ovarian secretion, thyroid therapy may increase the efficiency of small amounts of growth hormone or gonadotropic hormone reaching the peripheral tissues, and in young, undeveloped patients the use of thyroid alone in rather large doses may suffice to promote adequate growth and maturation. Such therapy, of course, should be persisted in only after chronic systemic disease, such as tuberculosis or nephritis, has been ruled out, because under such circumstances the increase in caloric turnover would only add insult to injury. Occasionally, in hospital practice, one finds a renal dwarf whose condition has been made worse by an ill founded hope of stimulating growth by thyroid therapy.

In addition to these precautions, there remains a large group of borderline or twilight conditions in which no clean cut syndrome can be diagnosed, but in which the patient responds far more strikingly to thyroid therapy than he would respond to placebos. Such symptoms as lassitude, overweight, inability to think and mild mental depression may in properly selected cases be benefited by thyroid, judiciously administered. Even obstinate constipation, based on mild hypothyroidism, may in itself justify such treatment. The dosage required for this type of therapy is often rather large and should not be persisted in without due precautions. A striking example of the abuse of this type of therapy has been reported by Richardson<sup>12</sup> in anorexia nervosa, a disease that occurs generally in young women suffering from a morbid desire for reduction of weight, even to

the point of emaciation. Because their basal metabolic rate is frequently under -25 per cent, the practitioner is tempted to give thyroid, especially in the hope that it may stimulate appetite. Such therapy only increases the emaciation and the mental agitation of the patient, and may be responsible in part for the not infrequently fatal outcome in such cases.

#### NEGLECTED OPPORTUNITIES

Whenever one encounters a patient suffering from cretinism or juvenile myxedema who has the physical appearance and mental status of a child, although mature in years, one realizes that such a patient represents a gross failure in therapy based on neglect. Such patients are likely to live many decades as a sad reminder of the fact that, had proper treatment been pursued consistently, they might have become useful citizens. In treating cretins or patients with juvenile myxedema, therefore, it is particularly important to begin early and to maintain active therapy continuously for many years. With present-day standards of therapy, however, the cretin has only about an I. Q. of 60, whereas nearly all cases of juvenile myxedema attain this level of intelligence.<sup>13</sup> This difference presumably reflects the lack of iodine or thyroid hormone experienced by the cretin during intrauterine life, as witnessed by the presence of cretinoid goiter at birth. With better therapy, persistently adhered to, Rolleston<sup>14</sup> believes the prognosis to be correspondingly brighter.

All intergrades exist in degrees of thyroid lack, ranging from the striking imbecilic dwarf to young people who do not have quite enough thyroid secretion to enable them to grow up physically and mentally. Some patients with delayed puberty, for example, may require merely extra thyroid hormone to increase their stature and to facilitate sexual maturity. When treated with rather large doses of thyroid for several years, such persons may grow many inches in height and undergo a complete change in personality. Such a case has been reported in detail by Zondek.<sup>15</sup> The obscurity of these early hypothyroid problems is illustrated by a case seen recently at the Boston City Hospital.

A 14-year-old schoolboy was referred for study with a chief complaint of enuresis. The past history was negative except for measles and chicken pox in early childhood. He had always been active and well, although a trifle small for his age and slightly backward in school. His father was somewhat perturbed at his immaturity and lack of interest in the opposite sex.

On physical examination, the patient was found to be poorly developed and moderately well nourished. The

scapulas tended toward the "wing" position. There was moderate left dorsal scoliosis. The external genitalia were those of a boy of 10. The testes were descended, and about 1.5 by 1.0 cm. in size. Pubic and axillary hair was absent. The skin was somewhat dry, but not cold. The pulse rate was 70. The weight was 8 pounds under standard, according to Bardeen's tables.<sup>16</sup> X-ray study showed epiphyseal ossification at least 1 year delayed. The basal metabolic rate was -13 per cent by the Boothby-Sandiford modification of the Dubois standards. The plasma protein-bound iodine was 3.7 microgm. per 100 cc., that is, the level found in incipient myxedema in the adult. The 17-ketosteroid excretion for 24 hours was somewhat subnormal for his age.

The patient was placed on thyroid U.S.P., beginning with  $\frac{1}{2}$  gr. and increasing cautiously to 3 gr. daily. Special care with the diet was advised, and general hygiene instituted.

Obviously, this therapy must be undertaken before the epiphyses have finally closed, and it must be accompanied by appropriate supportive measures, such as general hygiene and good diet, and often with a certain amount of psychiatric or social adjustment. Frequently, too, other hormones may be supplied to advantage, but it is sometimes surprising how much the addition of thyroid alone will accomplish. Thus, Foster and Thornton<sup>17</sup> have successfully used thyroid in the treatment of menstrual irregularity in certain groups of cases. There is ample scientific background for this therapy apart from clinical experience, because it has been demonstrated clearly that the peripheral tissues utilize small amounts of growth hormone<sup>18</sup> and of sex hormone more effectively when adequate thyroid secretion is present. Indeed, hens lay more eggs<sup>19</sup> and cows give more milk<sup>20</sup> under similar circumstances. In the use of such therapy, due consideration should be given not only to the normal growth curve of the patient in question, estimated both in the light of standard statistics, such as those of the standard tables of Bardeen,<sup>16</sup> but also to the patient's forebears.

At present, too much attention is paid to the basal metabolic rate in the control of therapy. This is a useful objective method of deciding whether the patient needs more or less medicine, but the controlling factor ordinarily is the patient's own physiologic state. Barring untoward effects of troublesome degree, the patient should receive enough medicine to rectify the complaint. This is merely common sense, but it is often lost sight of in routine therapy. In general, the more the drug is needed, the lower the dose required to rectify the disorder.

Certain cases of mistaken diagnosis may sometimes be disclosed by a sluggish response to thyroid therapy. For example, loss of hair from natural causes may occasionally be mistaken for evidence of hypothyroidism, or chapping of the skin

and lips in winter due to alkaline soaps or to vitamin deficiency may similarly be misinterpreted. In the dry eczema of old people, however, the so-called "eczema hiemalis," the judicious use of thyroid may lead to increased sweating and secretion of the sebaceous glands sufficient to make tolerable an annoying condition. When such therapy is undertaken in older people, of course, particularly during cold weather, there is always a certain risk of overstraining the heart.

#### NEW PROBLEMS

In recent years, special interest has been focused on cases of Graves's disease without hyperthyroidism, exhibiting the syndrome that Brun<sup>21</sup> has termed "exophthalmic ophthalmoplegia." Such patients as a general rule do not have in abnormally high basal metabolic rate; indeed they may show a subnormal basal metabolic rate, especially if they have been treated previously by subtotal thyroidectomy. A high concentration of thyrotropic hormone is usually found in the urine, unlike that of classic hyperthyroidism. The average surgeon is tempted in such cases to operate a second time and remove more of the gland, but accumulating experience indicates that this merely exaggerates the disturbance. At the present time, one useful method of therapy seems to be that of rather high dosage of thyroid, usually combined with iodine.<sup>22</sup> The large doses of thyroid, of course, elevate the basal metabolic rate, and such patients must pay for the preservation of their eyesight by a certain number of months of artificial hyperthyroidism, exogenous in origin. It may even be necessary to use repeated injections of thyroxin in solution by vein, but this situation is very rare and such treatment should be carried out only in a hospital. Under favorable circumstances thyroid therapy may check the advancing exophthalmos and may eventually lead to satisfactory recession of the globe. In the course of such a program, due consideration must obviously be given to the cardiac status and similar variables. In my experience in a large hospital, this group has comprised over one tenth of the cases in which the thyroid status has been questioned.<sup>23</sup> Some of them were patients who had once been operated on and who returned because of recurrent nervousness and prominence of the eyes, often asymmetrical.

It is not generally realized that many routine cases of Graves's disease show moderate increase in exophthalmos after thyroidectomy if careful measurements are made. Indeed, most clinicians believe the reverse to be true, because this increased exophthalmos is obscured by the return of the upper eyelid to its normal position. It seems

likely that the cases of malignant exophthalmos are simply extreme examples of a mechanism that occurs generally.

If the protein bound iodine is determined in the plasma of these patients before any iodine therapy has been used, it is frequently found to be normal.<sup>24</sup> Furthermore, if iodine therapy is given to such patients in large doses, the basal metabolic rate frequently falls to definitely subnormal levels. It has been suggested, however, that thyroid therapy, alone or combined with iodine, is often the procedure of choice, for reasons already described.

These questions also bear on the general problem of hyperthyroidism, because in cases of chronic Graves's disease of more than a year's standing, there is now some question of the best mode of therapy. In many of these patients, the iodine metabolism seems to be at approximately normal levels, perhaps because the thyroid's reserve of iodine has been exhausted. Nevertheless, in patients subjected to subtotal thyroidectomy, the disease is prone to recur. For this reason, Lacey and his colleagues<sup>25</sup> have recommended a radical resection under these circumstances. The tentative opinion has also been advanced by other workers that iodine therapy in these cases may supply the raw material for a renewed outpouring of thyroid hormone in great excess. Still other clinicians fear that ultimate cardiac decompensation will take a heavy toll if nearly all cases showing even mild symptoms are not operated on. Obviously, the final word cannot be stated at present about this special group of cases. It may, however, be a useful confirmatory test to find that the plasma protein bound iodine before therapy is normal even though the apparent basal metabolic rate may be somewhat increased.<sup>24</sup> Should these cases, carefully selected, receive thyroid medication?

Another point of interest that requires further clinical experience is the use of commercial thyroid preparations in older patients with hypothyroidism and in those with frank cardiovascular disease. Meyer and Yost<sup>26</sup> have presented evidence that preparations of the whole gland may contain an unidentified material that accelerates heart action far in excess of the actual effect of the thyroid hormone itself. Indeed, they have fractionated such glandular preparations into one extract, which contains the thyroid hormone, and another, which contains the excessive cardioaccelerating material without the thyroid hormone. At present, more clinical experience is needed to determine the value of these findings, but already it seems possible that such an untoward effect may be avoided by using iodinated serum protein<sup>27</sup> in lieu of actual thyroid material.

The same thing may be said of certain purified

thyroid fractions now available commercially. In the treatment of cases subject to anginoid attacks, this point merits careful study.

\* \* \*

In summary, then, one should take advantage of the two properties of the thyroid hormone, namely, its maturing and its calorogenic effects, in rectifying disturbances in endocrine imbalance. In so doing, one must not fail to take advantage of the early years of life if growth and development are in question. In the later years of life, on the other hand, one must be careful not to outstrip the functional reserve of any organ or system in the body. It must always be remembered that all the endocrines are in league with one another, and that a change in thyroid balance alters pituitary, ovarian and adrenal function. Some of the symptoms of overdosage are usually mere nuisances, like diarrhea or oligomenorrhea. Others, such as the precipitation of heart failure or of Addisonian shock, may be rapidly fatal.

## PROBLEMS IN THE RECOGNITION AND TREATMENT OF TESTICULAR INSUFFICIENCY\*

ALLAN T. KENYON, M.D.†

CHICAGO

MANY of the properties of the testicular hormone have long been understood by physicians from years of acquaintance with eunuchs and eunuchoids, and certain influences of the synthetic androgens were accordingly readily foreseen. Other influences of the therapeutic androgens have, however, occasioned some surprise and have prompted re-examination of testicular functions less well grasped in the past, functions that still require much work for their proper understanding. The influences of testosterone and its relatives on sexual drive and on general body metabolism are effects that may shed new light on the place of the testis in human economy.

The exact composition of the hormone or hormones secreted by the testis is unknown. Testosterone, isolated from bull testes in 1935 and large-

ly obtained at present by the degradation of cholesterol, seems to repair castration defects very well, and to possess no exceptional or unnatural properties (Koch<sup>1</sup> and Moore<sup>2</sup>). Certain active esters of testosterone, the acetate and the propionate, are now used extensively in clinical and biological work, and owe their popularity to the fact that they are four times more powerful than testosterone itself in evoking growth of the prostate and seminal vesicles of the castrate rat when subcutaneous injections in oil are given.<sup>3,4</sup> This advantage seems to lie in a slower and more favorable rate of absorption from subcutaneous oil pools in this species and does not mean that these esters approximate the natural hormone in composition. A similar and even more striking enhancement of effect is provided by implantation of testosterone in pellets under the skin.<sup>5</sup> It is difficult to say what difference it will make when the precise form of the natural androgenic secretion is

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1941.

known, but reservations derived from this ignorance should be kept in mind. Such reservations are applicable especially to the consideration of methyl testosterone, which retains much of its activity on oral administration.<sup>6</sup> It is certain that this substance does not increase urinary androgen excretion when given orally to man nearly so much as testosterone does.<sup>7,8</sup> The significance of this peculiarity is not clear, and most careful examination is desirable before the full equivalence of methyl testosterone to the testis in a clinical sense is accepted.

When testosterone or one of its active relatives is given in proper dosage to a eunuch or a eunuchoid or to a child, one of the first and most consistent and distinct reactions induced is an increase in frequency, intensity and duration of erections of the penis.<sup>9-11</sup> This response may occur within a few hours of the initial dose, usually within a few days, and may be intense enough to reach priapism. It is often accompanied by erythema and edema about the genitalia and by considerable increase in sexual desire and capacity for intercourse. As the anatomic responses to the androgens progress, this heightened genital irritability often subsides somewhat but still remains fairly distinct. This effect recedes on cessation of treatment in the majority of cases, and is not consistently simulated by responses to placebos.

It is true that the sexual activity of several lower forms of animals had long been known to be strictly dependent on testicular hormones,<sup>12</sup> but experience with man had suggested an overwhelming importance of mental attitudes for sexual drive. Although castrate men often complained of waning potency, in others both inclination and capacity for intercourse were at least to some extent retained for years.<sup>13-14</sup> It was accordingly tempting to interpret the irregular depression of sexual power after castration as psychogenic, occurring by virtue of the subject's unhappy expectations, rather than by virtue of his loss of hormones. The erotogenic property of the therapeutic androgens has, however, restored confidence in the validity of the eunuch's story of impaired sexual drive. Man in his evolutionary progress has not lost the primitive sensitiveness to erotogenic testicular secretions, but with the elaboration of cerebral function and the permeation of consciousness by sexual and quasi sexual concerns, his nervous system has grown less dependent on hormonal excitation and more dependent on the countless factors shaping emotional life. From individual to individual, the resultants of humoral and nervous or psychic forces must vary greatly. The former factor still requires attention throughout the study of the pathology of the sexual impulse.

How useful is testosterone in enhancing the sexual drive in those many men, apparently sound physically, who nevertheless suffer from sluggish sexual desire and inability to perform normal coitus? It is conceivable that the desire and potency of certain men might be increased beyond that induced by their own normal androgens sufficiently to overcome fears and misgivings that had frustrated the original normal sexual drive. The answer as thus far known is not very hopeful. Rubinstein and Kurland,<sup>15</sup> Rennie, Vest and Howard,<sup>16</sup> and Kenyon et al.<sup>17</sup> have injected testosterone propionate into normal men, and in no case has the slightest effect on frequency of erections or sexual desire been recorded. Although hypernormal excretion of urinary androgens<sup>18</sup> and nitrogen retention<sup>17</sup> can be readily induced, the sexual drive is unaffected. This is clearly no final statement; individuals vary too much for that, but it seems unlikely that the sexual drive natural to any person with sound testes can often be readily increased.

Occult testicular insufficiency, however, may exist in some impotent men. After castration of the man who has once reached sexual maturity or after discontinuance of effective androgen therapy in the hypogonad, the deep voice remains, the penis may not recede to an unmistakably hypoplastic state, genital, trunk and facial hair falls out slowly and irregularly, and considerable amounts of inactive prostatic tissue may remain palpable. It is thus quite possible that a significant reduction in the amounts of testicular secretion for fairly long periods may go undetected if observation is confined to these sluggish and unquantitative physical criteria of androgen production. It would be easy indeed to invoke psychogenesis at such times. Unfortunately, assays for urinary derivatives of the testicular hormone have not been widely applied to impotent men. Zones of overlap apparent between those with normal testes and even those who are grossly hypogonadal will probably restrict the usefulness of such procedures, however, to some extent at least. One is thus left with the therapeutic trial, easy to apply and hard to interpret. Although benefit in the treatment of impotent men with testosterone propionate has been reported, the extensive experience of Rennie, Vest and Howard<sup>16</sup> indicates that such benefit is not often secured.

Carmichael, Noonan and Kenyon<sup>19</sup> treated, with testosterone propionate, 19 men who suffered variously from inadequate sexual desire, failure to secure or sustain erections at the time of coitus, and premature ejaculation. With the exception of one man who had atrophic testes but a normal penis, prostate and secondary sex characteristics,

none suffered from pertinent organic disease. Twenty-five milligrams, intramuscularly, three times weekly was given because this seemed adequate replacement dosage in patients with gross testicular defects. Relief of the impotence was obtained in 7 of the patients—2 children were begot by these men; 11 patients were unaffected. Unfortunately, the successes do not bear close inspection. In no case was cessation of treatment or substitution of inert sesame oil for the androgen accompanied by such relapse within a few weeks as would be expected if there was genuine dependence on the testosterone propionate. At first, the patient with atrophic testes seemed to distinguish between testosterone and sesame oil, but in the end he wearied of treatment and carried on successfully for at least a month after the last injection, so that dependence was quite doubtful. The only conservative interpretation of these results is that any benefit secured was psychologic—suggestion either pure and simple or suggestion arising from an initial physiologic excitation with successful coitus and restored confidence.\*

It still remains to be seen whether testosterone propionate will cure any patient whose impotence is not amenable to rather simple inquiry, explanation and reassurance, or to treatment by placebo. My guess is that in time one will find such people—those with occult testicular insufficiency whose hormone production is below their particular nervous thresholds for adequate sexual drive. Perhaps they will be found among older men whose hormonal production is normally declining, but, in any event, they are probably a small minority of impotent men. In the search for these, however, I believe the therapeutic trial with androgens is desirable when simple psychologic methods fail. Twenty-five milligrams of testosterone propionate intramuscularly in sesame oil three times weekly, or methyl-testosterone, 50 to 100 mg., orally, daily for three weeks, should be adequate. Semen examinations at weekly intervals during such a procedure are wise. These dosages may in time reduce the number of spermatozoa and eventually cause their disappearance from the semen.<sup>21, 22</sup> Although such depression is always recovered from after androgens are stopped, so far as I know, there is no point in producing it. If such a therapeutic trial is successful, cessation of treatment or substitution of an inert substance may estab-

lish dependency on the androgen or lack of it. When treatment fails, recourse must be had to more elaborate psychotherapy.

The metabolic effects of the androgens have been of great interest to our group and, I believe, emphasize an aspect of testicular function that has received little attention. The data described here were gathered by Knowlton, Sandiford, Bryan, Koch, Lotwin and myself.<sup>16, 17, 18, 23</sup> Soon after the beginning of treatment of the eunuchoid with testosterone propionate intramuscularly, an increase in body weight is observed, amounting in our experience to 7 to 20 pounds at the maximum, and accompanied, on occasion, by slight edema of the face and ankles. The process is self-limited, a plateau appearing in forty to seventy days despite continued treatment. When the patient is examined on a constant food and fluid intake, a sharp decline in the urinary excretion of nitrogen and inorganic phosphorus, potassium, sodium and chloride is observed, while the urine volume declines and the body weight increases. During recovery from the testosterone effect, sodium and chloride, deposited largely in extracellular spaces, are quickly lost, together with associated water, while nitrogen, presumably stored as protein within cells, is still being retained. The inconspicuous losses of nitrogen for as long as thirty-eight days after cessation of therapy attest to the tenacity with which deposited protein is retained. The decline in urinary nitrogen is reflected completely in the urea fraction, and no increase in the concentration of nitrogenous constituents of the blood occurs. Fecal nitrogen is unaffected. When substantial creatinuria is induced by creatine feeding, this substance is also retained under the influence of the androgen.

The nitrogen retention has been previously described by Kochakian and Murlin<sup>24, 25</sup> in the castrate dog, and nitrogen and several electrolytes have been shown to be retained in the normal dog, as well as in an impotent man by Thorn and Engel.<sup>26</sup> In both rats<sup>27</sup> and monkeys,<sup>28</sup> creatine excretion is affected by androgens as in man. So far as work has progressed, therefore, the chemical reactions to androgens seem fairly general among animals. Exceptions in detail occur and will probably become more abundant in time as more species are studied.

The amounts of protein estimated as stored in the eunuchoid range from 109 to 395 gm. in ten to twenty-five days, far in excess of those conceivably going to the prostate and seminal vesicles. The curve of gain in body weight predicted from the protein stored, together with the associated water, falls short of the actual gain in weight and differs in its course from the actual weight

\*A possible complexity in interpreting the consequences of withdrawal of androgens should be noted, although it is well not to make too much of it at present. It may take several months for all sexual capacity to be completely extinguished in rats and rabbits when they are castrated after puberty,<sup>22</sup> and an immature drill (baboon) excited to sexual interest by androgens retained this interest for eighteen months after cessation of treatment.<sup>29</sup> Residual behavior patterns established by androgens and persisting after treatment must be considered. These may be difficult to separate from the results of suggestion in man.

curve. Retention of salt and water in extracellular spaces during treatment and their discharge thereafter probably account for the discrepancies.

It is of importance that nitrogen retention and salt and water retention have been produced in a subject with a craniopharyngioma in whom the anterior lobe of the pituitary body was reduced to a mere shred at autopsy.<sup>20</sup> It is therefore unlikely that these effects are mediated through the pituitary body.

The basal metabolic rate is increased by moderate dosages of testosterone propionate<sup>10 21</sup> In the extreme form of this effect, heat production may rise to levels as high as +40 per cent when large doses of methyl testosterone are used, as in the experiments of McCullagh and his co workers<sup>20</sup> The elevation is much less striking when amounts of testosterone propionate conceived as replacing the testes are given<sup>18</sup>

The retention of sodium, chloride and water is analogous to that produced by the chemically related adrenocortical substances in men and dogs with intact adrenal glands, an analogy well supported by the observations of Thorn and Harrop,<sup>30</sup> and Thorn and Engel<sup>20</sup> on the salt retaining properties of several sex hormones The analogy is incomplete, however, because the urinary excretion of potassium is characteristically increased by adrenal substances rather than reduced, as with testosterone propionate This partial imitation of one steroid by another is no new phenomenon Many other interesting examples could be cited

The retention of nitrogen, creatine, inorganic phosphorus and potassium suggests a somatotropic effect of testosterone propionate Papanicolaou and Falk<sup>31</sup> observed that testosterone propionate produced hypertrophy of the temporal muscles of the castrate male guinea pig and of the castrate or normal female There was also an increase in total muscle mass It is likely that new protein is deposited in muscle of man and probably elsewhere as well Attempts are now being made to record the strength and fatigability of the muscles of hypogonadal men after treatment with androgens, and the results are thus far encouraging.<sup>32 33</sup>

Recent evidence of great value demonstrates that, in certain boys, administration of androgens induces distinct gains in height Webster and Hoskins<sup>31</sup> found 8 hypogonadal boys to grow on the average of 1.36 cm. per hundred days before treatment with testosterone propionate, 3.6 cm. during treatment, and 1.56 cm. after treatment Browne and Ross<sup>33</sup> and McCullagh<sup>40</sup> added data of this same type, and Albright and his associates<sup>37</sup> secured increases in height in dwarfs with convincing physiologic evidence of anterior pituitary de-

fect Dorff,<sup>38</sup> using an identical twin as a control, secured an excellent demonstration of increased somatic growth in a short, poorly developed boy with chorionic gonadotropins, which stimulated androgen production by the boy's own testes It is of interest that early epiphyseal closure has not as yet been induced in such subjects From experience with older eunuchoids, however, and from the notorious early closure of epiphyses in children with precocious puberty, I should expect that carelessly large and protracted treatment of the young boy with androgens would in time effect epiphyseal fusion

The responsibility of the testicular hormone itself for the normal adolescent growth spurt thus becomes clear, and the reason for the association of precocious genital and somatic development in boys with testicular tumors is now, I think, apparent It is best, however, that such powerful properties of the androgens as these should be utilized by the physician in the young only when it is established beyond doubt that the patient's own testes will not spontaneously assert themselves. Under such circumstances, attempts at stimulation with chorionic gonadotropins are, I believe, the first choice Androgens may be used in event of failure

Two important therapeutic applications of the somatotropic properties of the androgens have been made recently by the group at the Massachusetts General Hospital, Albright, Parson and Bloomberg<sup>33</sup> have proved that testosterone propionate will induce immediate nitrogen and phosphorus retention and eventually calcium retention in those with Cushing's syndrome, and they have observed that these anabolic influences were accompanied by an improved sense of well being and physical efficiency They conceive these effects as counteracting protein wastage inherent in the disease Although further chemical support for the concept of protein loss as a critical metabolic event in Cushing's syndrome is admittedly necessary, guarded use of the androgens is desirable on the basis of this experience The risks of further depressing testicular function in the male, and of protracting the amenorrhea and of advancing the masculinization of hair, voice and clitoris in the female must be carefully assessed, and dosages sought that will, if possible, avoid them. Profound debility seems to be the essential indication for therapy, and the defect likeliest to be remedied There is no reason to believe that hypertension is affected by androgens

The metabolic responses to androgens in those with hypopituitarism are in time accompanied by significant gains in physical efficiency, according

to Albright et al.<sup>37</sup> Thus, the role of the testis in the metabolic consequences of pituitary defect requires examination. Careful use of the androgens, with due consideration of their possible disadvantages, will define the value of this tool in pituitary failure.

Unpublished work of our own indicates that testosterone propionate exerts at least most of its characteristic metabolic influences in the aged man. How important this is from the functional standpoint is unsettled.

Thus, one begins to think of the nongenital properties of the androgens and to seek means of gauging their value in testicular insufficiency and in other pertinent disease. The work is young and the future unsettled, but the prospects of making something interesting and useful out of the somatotropic effects of these compounds are not too bad.

#### SUMMARY AND CONCLUSIONS

The testis is of importance in initiating and maintaining the sexual drive and the capacity for intercourse in the human male, although this role is shared by nervous factors.

Testosterone and its active relatives, which are known to enhance sexual excitability in the hypogonad, have not as yet been shown to affect men with sound testes.

Occult testicular insufficiency, however, may play a role in causing impotence in men without obvious testicular defect. At present, however, it seems likely that such testicular responsibility is rare.

Testosterone propionate relieves perhaps a third of impotent men, but discontinuance of treatment or substitution of placebos is not followed by prompt relapses, so that true dependence on androgens is difficult to establish. Conservative interpretation necessitates regarding the benefit as due to suggestion. In the search for cases of true occult testicular insufficiency, brief therapeutic trials with testosterone and its relatives, critically examined, are worth while.

Testosterone propionate induces retention of nitrogen, creatine, inorganic phosphorus, sodium, potassium and chloride and causes an increase in body weight and in the basal metabolic rate of underdeveloped men. Growth in height of undergrown, underdeveloped boys has been established. It is suggested that certain of these effects at least occur independent of the anterior pituitary body. The reasons for the association of sexual development with enhanced somatic growth during normal adolescence and in precocious puberty are hence clearer.

These somatotropic properties of the androgens may be of benefit in the treatment of certain aspects of pituitary insufficiency and Cushing's syndrome. There is need for further exploration of these possibilities.

## THE USE OF FEMALE SEX HORMONES IN DISORDERS OF WOMEN\*

GEORGE VAN S SMITH, M D †

BIOAKLINE, MASSACHUSETTS

### FUNCTIONAL DISORDERS

THE application of the term 'functional' to any disorder means that known pathologic causes have been ruled out, that the real cause is unknown, and that the disorder may not be permanent. This word reflects the still unsatisfactory state of knowledge concerning those disabilities in women that are attributed to hormonal imbalance or lack, and indicates that any treatment must, for the present, be largely empirical. It also implies that all measures conducive to better general health, such as proper diet and elimination, emotional adjustment, regulation of habits, treatment of infected foci and anemia, and thyroid therapy, should be instituted, if necessary.

#### Amenorrhea

In patients with functional amenorrhea, whether primary or secondary, the really important aim is to produce ovulation. The available gonad stimulating extracts of anterior hypophyses or of pregnant mares' serum have been tried with only rare success because, perhaps, they are not potent enough or, more probably, because they stimulate antihormonal bodies, containing as they do for eign protein, or because the primary disturbance is not gonad stimulating insufficiency. Women with functional amenorrhea do not usually give the impression of having a pituitary disturbance. They either appear perfectly normal or are like her to show stigmas that one associates with adrenal hyperactivity. Evidence is appearing that more and more interrelates the adrenocortical and ovarian hormones. Analysis of this relation may give a clue to the cause and cure of functional amenorrhea.

The induction of simple anovulatory uterine bleeding is sometimes desirable for psychiatric reasons and may be accomplished by trials with the preparations mentioned above or with placental

hormone, chorionic gonadotropin or the steroid hormones, estrogen and progesterone.

#### Dysmenorrhea

Whether or not any endocrine imbalance exists in patients with essential or primary—that is, functional—dysmenorrhea remains to be demonstrated. What has been shown is that the symptoms may be mitigated or prevented by various hormones, provided they are given at such times during the cycle and in such amounts as to change the endocrine balance. The most dependable of these methods appears to be that of Sturgis and Albright,<sup>1</sup> who, by injecting estrogenic substance beginning on the sixth day after the start of menstruation, prevent ovulation and luteinization, thereby preventing the dysmenorrhea. This method is completely effective only during alternate months, but after a series of treatments, the intervening periods are likely to become less painful. At present, the cost to the physician of the estrogenic hormone for each painless catamenia induced is about \$13.00. Because most physicians hesitate to upset a physiologic process, even to alleviate an exaggeration of the usual response to it, and because of the high cost of hormones, they tend to temporize by means of general health measures and simple antispasmodics and analgesics, especially with girls, until the passage of time or pregnancy brings amelioration. In spite of a trial of all nonoperative measures, an occasional case of functional dysmenorrhea must be submitted to presacral neurectomy, an essentially curative procedure without known consequent disability, if well executed, although it is radical and apparently unphysiologic.

#### Premenstrual Distress

Another functional disorder, so-called "premenstrual distress or tension," includes any or all the following symptoms: premenstrual headache, often simulating migraine, depression, irritability, epigastric distress, nausea, sense of abdominal swelling and sore breasts. These symptoms

\*Presented at the annual meeting of the Massachusetts Medical Society Boston May 22, 1941

From the Free Hospital for Women

†Assistant professor of gynecology, Harvard Medical School, visiting physician and director of the Fearey Research Laboratory, Free Hospital for Women

are common, especially in women between the age of thirty-five and the menopause. Because they are accompanied by premenstrual increases of weight and occasionally by local or generalized edema, they are thought to originate from sodium and water retention associated with changes in sex-hormone metabolism. A simple treatment introduced by Greenhill and Freed,<sup>2</sup> consisting in sodium chloride restriction and ammonium chloride ingestion during the last two weeks of the cycle, is reported to give gratifying relief. This method is presumably treating the result and not the cause of the disturbance. Satisfactory relief may also be obtained by the administration of sufficient estrogen or progesterone in the second half of the cycle, or by giving fairly large amounts of oral estrogen daily throughout the cycle. This is perhaps a more physiologic treatment, since these patients are thought to have beginning ovarian failure, and such therapy is likelier to relieve the breast symptoms.

#### *Uterine Bleeding*

Functional uterine bleeding is usually no therapeutic problem in women over forty years of age, since radiation castration is so simple and dependable, although it is neither ideal nor wholly desirable. Complete examination under anesthesia is a necessity in these patients, because it is the only way of making reasonably certain that cancer is not present. In younger women who are obviously not going to have a remission to normal cycles, either spontaneously or from general constitutional treatment with emphasis on the administration of thyroid and iron, it seems wiser to try curettage and then hormones before resorting to more radical surgery or temporary inhibition of the ovaries by radiation, especially since there can be no positive assurance that either of these procedures will be permanently curative in any patient, unless performed radically enough to involve the possibility of permanent damage. Chorionic gonadotropin, when injected during the flow in daily doses of 1000 to 2500 international units for four to eight days, may be expected to stop functional uterine bleeding at least temporarily in about 75 per cent of cases and to result in apparent cure in about 40 per cent. If it is to be effective, chorionic gonadotropin must be given in large doses, for smaller amounts may aggravate the bleeding. Unfortunately, large injections may be painful. Equine gonad-stimulating hormone has not yet been found to be of dependable value in this condition. Testosterone in large daily dosage, although it is costly, stops functional uterine bleeding, apparently through the desirable effect of temporary ovarian inhibition. Progesterone ap-

pears to be the ideal drug, at least for inhibiting bleeding in a physiologic manner, even if it may not remedy the basic cause, but thus far it has been too expensive for extensive clinical studies.

#### *Habitual Abortion*

Although habitual or threatened abortion or threatened miscarriage involves various and complex possible causes, the known necessity of adequate progesterone for normal gestation indicates its use in these precarious states. Circumstantial evidence implies that much more progesterone is secreted than appears as urinary pregnandiol. Hence, I believe it might be of more value than reports at present suggest if it is given in much larger doses. Furthermore, I believe it would be more clearly valuable if injected with estrogen.

In experimental work, estrogen is necessary for the optimum effect of progesterone and for stimulating and maintaining luteal activity. That it is also necessary for progesterone activity in human beings is indicated by the fact that its increases and decreases precede or accompany increases and decreases of progesterone both in menstrual cycles and in pregnancy, including those cases of threatened abortion in which changes in these hormones have been detected. Evidence of progesterone secretion is never found in the absence of estrogen. Conversely, secretion of estrogen without consequent or concomitant secretion of progesterone does occur and may result in typical functional uterine bleeding. In fact, all the available evidence shows that these two hormones are complementary, that they enhance and regulate each other's properties, and that they are physiologic companions. The idea that estrogen may cause abortion in human beings may be completely disregarded, since otherwise we should all certainly by now be acquainted with such use.

These considerations make me optimistic that better results will be achieved in all conditions in which estrogen or progesterone alone has already seemed of value just as soon as one becomes accustomed to the idea of administering these hormones in combination and their cost drops to a practical range.

#### *Sterility*

Functional sterility involves so many factors in each partner that no straightforward indication for the use of hormones has been determined. Poor semen and failure of ovulation continue to complicate trials of gonad-stimulating factors, but general constitutional measures and postcoital insufflation during the time of possible ovulation should not be disregarded. The oral administration of estrogenic

substance in moderate amounts for months has often seemed worth while

#### OTHER DISORDERS

##### *Senile Vaginitis*

Senile vaginitis severe enough to be symptomatically disturbing is a relatively rare condition, and usually responds to simple antiseptic measures and persistent cleanliness. The characteristic slight staining demands thorough investigation. To hasten cure both by its local effect in increasing acidity and stimulating activity of vaginal epithelium and by its general beneficial effect in the menopause, estrogen is helpful if given in large dosage. I think that a combination of estrogen and progesterone will in time be found even better.

##### *Vulval Itching and Irritation*

Itching and irritation of the vulva, especially with involvement of the perineum, the perianal region, the intergluteal fold and the upper inner thighs, suggest urinary sugar and the vaginal trichomonal or fungous infection as causes. Cleanliness and a fair trial of a mild sulfur and salicylic acid ointment are likely to give prompt relief if a fungus is the cause. If, however, the vulva alone itches and is whitened, thickened and crinkly, more deep seated and irreversible pathologic changes are present. Although there is as yet no evidence to justify a fear that the use of hormones may cause cancer in human beings, in this site or elsewhere, prolonged intunctions with estrogen in tissues of known potential malignancy do not seem

warranted and, being only palliative, delay the relief that attends the simple operation of complete superficial vulvectomy.

##### *Cystic Disease of the Mammary Glands*

The background of cystic disease of the mammary glands and its end stage is so uncertain that no place for any hormone in treatment is apparent.

\* \* \*

The practical use of female sex hormones in disorders of women is indeed still limited. Clinical trials are vastly easier than fundamental investigation, but until more basic knowledge is acquired, voluminous contradictory and poorly controlled results will continue to appear and bewilder even those who are supposed to have more than average familiarity with the field. Many physicians believe that they are behind the times in the matter of hormone treatment and that others can accomplish more with hormones than they can. From my own experience, in practice and laboratory and from a fairly intimate acquaintance with the literature, I can assure them that they are not really behind the times, for just as soon as a treatment is found to be clearly and consistently effective, it rapidly comes into universally accepted use. Only estrogen, alone, in the treatment of the menopause has reached that goal.

## THE CURRENT STATUS OF FEMALE SEX HORMONES\*

ROY G. HOSKINS, M.D.†

BOSTON

A DECADE ago, endocrinologists were confident that within a few years the new knowledge that they had secured would come into productive use to solve many of the problems of gynecology. Toward the end of that decade, an eminent gynecologist, who had himself contributed a great deal to the newer developments, stated in effect that, except for a certain amount of amelioration of the discomforts of the menopause, gynecic endocrinology had contributed practically nothing to the welfare of women. The condemnation was no doubt too sweeping, but it serves to raise the question why the discoveries of the investigators have failed to yield more substantial clinical returns. It is the chief purpose of this paper to reconsider some of the fundamental evidence for the light that may be shed on this problem. A second purpose is to suggest certain possibilities for the extension of clinical research, with the idea of making the physiologic discoveries more fruitful.

## PHYSIOLOGY

Among the many important discoveries regarding the sexual physiology of women, one of the most meaningful is that destruction of the anterior lobe of the pituitary gland leads to a profound depression of the reproductive structures and functions. The further discovery that the sex depression can be corrected by the use of pituitary grafts or extracts shows that it is due to the loss of one or more stimulating hormones. By chemical manipulation of the extracts, the stimulating material has been obtained in high concentration and shown to be of protein nature. It is known as gonadotropin. More recently, gonadotropin has been separated into two chemical fractions, pure or nearly pure, one of which stimulates the corpus luteum and one the follicular apparatus. These fractions are LH (luteinizing hormone) and FSH (follicle-stimulating hormone). The fundamental controlling influence of the anterior lobe of the pituitary gland on the ovaries is now firmly established. This key fact must be kept in mind in practical research on the sex functions.

But the ovaries—including the corpora lutea—also exercise a large measure of control over the pituitary gland. This arrangement leads to a com-

plex set of interrelations that should also be taken into account in attempting to apply physiologic knowledge to problems of reproductive dysfunction.

The best known feature of ovarian physiology, as such, is the secretion of the estrogenic hormone. This is formed chiefly by the follicular apparatus. The secretion reaches full tide at the midmenstrual period when the follicle is ready to discharge an ovum. It is at this time that the phenomenon of heat occurs in animals and that concern with heterosexual matters is at its height in women. As the estrogen output has been increasing, it has been exercising a cumulative inhibitory effect on the anterior lobe of the pituitary gland, so that when estrogen is at flood tide, FSH is at ebb. The ovary is thus deprived of its pituitary support, and estrogen secretion, in its turn, largely ceases. Then, after a lag, the brakes are released, that is, the inhibition of the pituitary gland wears off, the secretion of FSH begins again, causing the secretion of more estrogen, and the total cycle is repeated. Thus, the ebb and flow of gonadotropin bring about an ebb and flow of estrogen, and vice versa.

The actual drive behind both sets of cyclic events is, of course, the secretion tendency of the individual cells, but the factor that makes for cyclicism is largely the lag in the influence of each of the hormones on its target organ. There is some evidence, however, that the cyclicism resides more in the pituitary gland than in the ovary—the evidence being chiefly that spayed monkeys, under the constant influence of estrogen supplied at a minimal effective rate, can sometimes be made to menstruate regularly.

But this relation of FSH to estrogen is only half the story. The trend of recent evidence is to show with increasing clarity that a similar relation exists between the luteinizing hormone and the corpus luteum. Although explicit quantitative data are yet lacking, the end results indicate that, while the FSH tide is receding, the LH tide is rising and thus ensuring the development of a new corpus luteum. This structure begins at once to secrete progesterin. After a few days, the progesterin level reaches a point at which the production of LH by the pituitary gland is halted, and progesterin formation then wanes. Thus, a second reciprocal series of cyclic events is set up. These alternate in phase with the FSH and

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 22, 1941.

†Research associate in physiology, Harvard Medical School, director of research, Worcester State Hospital and Memorial Foundation for Neuro-Endocrine Research.

estrogen cycles. The total result is like that of two seesaws operating side by side so that while the end of one is going up the corresponding end of the other is going down.

The consequence of this double reciprocating arrangement is that on every day of the month the four hormones concerned—LH, progesterin, FSH and estrogen—are normally present in different absolute amounts, as well as in different proportions of one to another. It is only by this nice and constantly shifting system of checks and balances that the normal menstrual cycle is maintained. Any serious dislocation of the fourfold balance spells menstrual disorder.

#### PRACTICAL AND THEORETICAL APPLICATIONS

Although a certain amount of palliation of menstrual disorders can sometimes be achieved without taking these fundamental facts fully into account, actual restoration to normality, which is of course the real goal of the therapist, cannot be obtained.

First, there is an important consequence of the fact that the gonadotropins are protein substances: if given at all, they must be administered in such a way as to escape digestion. This fact places a considerable limitation on their practical use. Secondly, the gonadotropins, LH and FSH come into action alternately, and if Nature is to be imitated at all closely in the control of cyclic dysfunctions, they must therefore be given in sequence, with due consideration of the proportion of the cycle in which each is dominant. If both the gonadotropins are given together, they must necessarily be largely self-defeating remedies: what is gained by the promotion of estrogen secretion in phase is lost by the promotion of progesterin secretion out of phase, and vice versa. But at the present time, only mixtures of the two pituitary gonadotropins are available. Thus, an impasse is reached, and at a stroke, half the theoretical possibilities of ovarian control are lost. The practical conclusion of the matter is that pituitary gonadotropins as at present available are probably not worth using.

However, according to current findings in Cohn's<sup>1</sup> laboratory, the pituitary FSH is an albumin whereas LH is a globulin; hence, they could perhaps be prepared separately in commercial practice without too great difficulty. However, another difficulty is inescapable: the yield is very small, and these two hormones are consequently too expensive for the use of anyone but investigators and millionaires.

Less expensive than the pituitary hormones are the various chorionic gonadotropins that are ob-

tainable from human placentas and pregnancy urine. These, however, have the physiologic function of promoting the relatively steady state of pregnancy and not the cyclic events that are principally concerned in this discussion. Whether these products could be chemically manipulated to give fractions having purely follicle-stimulating and corpus-luteum-stimulating properties remains to be determined. The mare-serum gonadotropin was formerly believed to give pure follicle stimulation, but more recent work shows that it also influences corpus-luteum development. In recapitulation, then, the successful therapeutic control of cyclic ovarian functions in large measure still awaits the production of separate follicle-stimulating and corpus-luteum-stimulating hormones.

Even when such preparations become available, however, another practical difficulty will still remain. In the natural scheme of things, the gonadotropins flow into the blood stream, not at a constant rate, but with everchanging ebb and flow. Therefore, the therapeutic mimic, if he is to conform to Nature, must change the dosage every day in the month, and at some stages of the cycle he must give both hormones together.

A partial escape from the manifold difficulties of gonadotropin therapy lies in efforts to control the secretion of these substances by the patient herself. The therapist may elect to give the ovarian hormones, estrogen and progesterin, instead of the gonadotropins, and may depend on their influence on the regulator gland to maintain the ebb and flow of the gonadotropins. The same considerations regarding sequence and shifting dosages apply, of course, to the ovarian hormones as to the gonadotropins.

Is this all so complex as to add up to therapeutic nonsense? It should be noted that the complexities are Nature's doing and not the endocrinologist's. The facts can only be faced. Unless physiologic conditions can be restored in the ailing woman, she must necessarily remain in a pathologic status. It is true that any one of the four hormones can be given arbitrarily in any dosage desired and, so given, may by good luck restore normality on some day of the cycle, but by the same token must necessarily induce abnormality during the other twenty-seven days. The best, therefore, that can be hoped for by any system of constant dosage is the substitution of one abnormal condition for another. It may or may not be better than the abnormality that it supersedes. As a matter of clinical fact, it is sometimes better, and the patient secures considerable relief. To determine just how much clinical results could be

improved by following a stair-step pattern of dosage levels of the sex hormones and using them in normal temporal sequence, more research is needed.

Not only the slopes of the sex-hormone production curves but also the quantitative levels at which the curves are set are important characteristics. Estrogen, for example, is both a stimulating and a depressing agent, the end effect depending largely on the amount that is used. In the lower dosage range, it stimulates the uterus and various other secondary reproductive structures. It also supports the corpus luteum and facilitates the metabolism of its hormone, progesterin. There is some evidence that it may also stimulate the anterior pituitary gland and the ovary itself. But as the blood-estrogen level increases, the effect shifts predominantly to depression, and especially depression of FSH production. Through this depressive range, estrogen when given as a sex stimulant is largely a self-defeating remedy. By analogy, it is as though the motor of a car were supplied with more gasoline but with the brakes simultaneously tightened. The car under such conditions may actually be brought to a standstill. Finally, by increasing the dosage still further, the braking effect can largely be overcome and stimulation of most of the target organs secured. To return to the analogy, the car can be forced to go ahead even with the brakes set, but that procedure is not good for the car. Likewise, a woman with a vital part of her anterior pituitary gland paralyzed is certainly not in a good physiologic condition. The best that can be hoped for with unphysiologic dosages is some sort of passably good performance in a fundamentally maladjusted organism.

It is possible that further research will show that, in a substantial proportion of clinical cases, when stimulation is desired, more could be accomplished with estrogen by keeping the dosage within the primary stimulating range and giving it time gradually to exert its influence than by administering the abnormally large doses that are commonly employed when stimulation is desired.

In the use of the gonadotropins and primary sex hormones, various difficult problems of diagnosis are, of course, involved. In any type of replacement therapy, it is essential to know just what is to be replaced and just how extensive is the deficit that is to be corrected. However, an adequate consideration of these problems is impossible here. It may only be reiterated that menstrual disorders may be due to either pituitary or ovarian misbehavior. Better results would presumably be obtained with gonadotropins in the

one event and with primary sex hormones in the other—provided, of course, that these are given in appropriate dosage and sequence.

So far as I know, there is only one clinical situation in which current therapeutic practice compares at all adequately with physiologic principles. That is in the treatment of the menopause. This is a time of transition in which the waning production of ovarian hormones takes the brakes off the anterior pituitary gland and allows the body to be flooded with gonadotropins. The exuberance can be checked in any one of several ways and, according to present evidence, with about equal success. X-ray treatments can be directed at the pituitary gland, or primary sex hormones in depressing dosages can be given. Estrogens or androgens are about equally effective, except that if the dosage of androgen is too high the woman may grow a mustache or show other evidence of masculinization. There seems to be, however, a fairly wide margin of safety.

Another striking fact, which the practical therapist conventionally ignores, is that women produce nearly as much male sex hormone as men. The estrogens and androgens apparently circulate in fairly definite proportions, one to the other. Just what Nature is about in setting up this curiously paradoxical state of affairs remains, so far as I know, a complete mystery. But it seems to be necessarily a fact that whenever estrogen is administered in significant dosage the normal estrogen-androgen ratio is disturbed. It is possible that the arrangement is meaningful and that the therapist may have to reckon with that meaning before his results become entirely satisfying either to himself or to his patients. As an empirical procedure, it might be worth while to study the comparative effects of estrogen given by itself and also given with balancing doses of androgen—both being kept within physiologic limits of quantity.

Another theoretical, if not practical, complication in gynecic endocrinology is that the adrenal cortex is able to produce sex hormones, both estrogens and androgens. This potentiality is most easily recognized when cortical neoplasm or hyperplasia results in the masculinizing of women or the feminizing of men. Sex hormones are often found in unusual amount or type in the urine of such patients. What part the adrenal glands may play in cyclical sex activities of normal women is, so far as I am informed, completely unknown. It is possible that a significant relation exists, and it may be one of practical moment; this is, of course, a proper subject for research.

An additional hormone that has considerable

influence on the reproductive processes is prolactin. It, too, is an anterior pituitary derivative. Although prolactin has been discussed mostly in relation to mammary gland activity, it has an essential relation with the sex glands proper. As Riddle<sup>2</sup> showed early in the course of his studies, this hormone has a rather marked depressing effect on both the ovaries and the testes. In rodents, at least, it also has a remarkable effect on the instinctual drives, arousing strongly the maternal impulses. By its use, a virgin rat can be made to adopt and mother not only baby rats but also mice, rabbits or even squabs. Nature apparently makes some little use of prolactin as an agent for depressing the ovaries of women, thus producing amenorrhea during the early weeks of nursing. Whether aberrations of prolactin secretion play any significant role in the ordinary menstrual disorders is, I believe, quite unknown. Further research might reveal practical aspects of that possibility. What therapeutic use prolactin might have further in the prevention of pregnancy or in the assuagement of overaridant amatory proclivities in women also seems to be an appropriate matter for clinical investigation.

The purpose of this discussion has been chiefly to suggest some of the possibilities of research that might improve the yield of practical clinical results. The fundamental physiology is complex; the application of that physiology in clinical practice will probably have to be equally complex to give the best results. Particularly, stair step dosage and proper timing of alternating materials will perhaps prove to be absolutely necessary conditions to success in many cases. Except for the treatment of menopausal disturbances, there appears to be little hope in the traditional patterns of drug therapy. There is not now and probably never will be any effective easy way to practice gynecology by using endocrine therapy.

#### SUMMARY AND CONCLUSIONS

Some of the older and the newer physiologic evidence is re-examined in relation to potential clinical applicability. The normal cyclic sex behavior of women is the result of several complexly interacting controlling factors. Serious derangement of any one factor can lead to clinical dysfunction. The goal of the therapist is to restore normality by substituting physiologic for pathologic ovarian behavior. To accomplish this, the factor or factors at fault must be recognized and appropriately dealt with.

The fault may lie in the anterior pituitary gland. Any one or more of three hormones may be involved—two gonadotropic factors (FSH and

LH) and prolactin. These are protein bodies and must therefore be administered parenterally. They are expensive. The first two should be administered in proper alternating sequences. At present, only mixtures are available; hence gonadotropic therapy is theoretically self-defeating. Pregnant mare preparations give purer but not entirely specific effects. Prolactin serves under normal conditions as a gonad depressant; research may show it to have some clinical value aside from its stimulating effect on the mammary glands.

More practicable for substitution therapy are the sex hormones proper, the estrogens and progesterone or their synthetic substitutes. These, too, must be given alternately and in phase, if their natural production is to be imitated. Each depresses the production of its corresponding gonadotropin.

All four of the gonadotropic and primary sex hormones are secreted at daily varying rates so that the blood titers, as well as the proportions existing naturally among them, differ on each day of the month. Restoration of normality therefore necessitates stair step dosages, in addition to sequential administration.

The estrogens have a three phase influence, depending on dosage. In the smallest effective range, pure stimulation seems to result. In the intermediate range, the anterior lobe of the pituitary gland and the gonads are depressed, so that the total effect may be depression. In the highest ranges, the depressions may be overcompensated. This is the conventional but pathologic range that is commonly employed. Such overdosage is theoretically indicated only in treatment of the menopause.

The adrenal cortex is capable of forming several sex hormones. More research is needed to determine whether they play a role in the normal sex activities of women and thus enter into the therapeutic equation.

Women secrete both male and female sex hormones in somewhat constant proportions. Research is needed to determine whether the male hormone plays a physiologic role and what its therapeutic value in conditions other than the menopause may be.

It is emphasized that the normal physiologic mechanisms are in part not yet known and that Nature's use of the sex hormones, even as now known, is but poorly imitated by the practical therapist.

seconded by Dr. Fitz, and it was so ordered by vote of the Council.

### *Study of the Practice of Medicine by Unregistered Persons*

The chairman, Dr. Richard Dutton, Middlesex East, reported that the committee had nothing to report. It was moved by Dr. Lund and seconded by Dr. Fitz that this report be accepted, and it was so ordered by vote of the Council.

### *Committee to Meet With Massachusetts Hospital Association*

There was no response from the chairman, Dr. Howard M. Clute, Suffolk.

### *Medical Preparedness*

Dr. Fitz reported that his committee had nothing to report. It was moved and seconded that the report be accepted, and it was so ordered by vote of the Council.

### *Committee to Examine WPA Records*

Dr. Guy L. Richardson, Essex North, before offering his formal report (Appendix No. 10), spoke of a physician who complained to his Senator that he was not getting enough WPA work. Dr. Richardson said that this situation was bad, and added that the physician in question had been advised to send in the full matter of his complaint, whereupon the matter was dropped.

Dr. Richardson spoke of hernias which developed in WPA workers and said that, except in emergency, it was the ruling of the WPA authority that, if these hernias were to be operated on, the operation would have to be performed in the Marine Hospital.

Dr. Richardson moved the acceptance of the report. Dr. Conley seconded the motion.

Dr. William E. Browne, Suffolk, said that the WPA officials were generally very fair. He said, however, that this particular ruling might be very hard on the person who developed a hernia in North Adams and had to go to Brighton to have it repaired. Dr. Bearse was also critical of this ruling. Dr. Richardson said that his committee had protested the ruling, which had come from the Commission in Washington, because of the unfavorable experience which it had in these cases when the ruling was otherwise. Dr. Peirce H. Leavitt, Plymouth, said that it was an unfair ruling and that he hoped the committee would continue to try to have it changed.

There was further discussion by Drs. Bagnall, Richardson and Browne. The question was demanded from several sources in the Council. Dr. Ober put the motion, and it was passed.

### *Maternal Welfare*

There was no response from the chairman, Dr. Judson A. Smith.

### *Study of Practice of Medicine*

Dr. Dwight O'Hara, Middlesex South, read the report (Appendix No. 11) and moved its adoption. This was seconded by Dr. Hornor.

Dr. Mongan asked what was the present status of the law in regard to the standards of medical education in Massachusetts. Dr. O'Hara said that it was his understanding that the matter was in the hands of the Approving Authority, which is empowered to act in 1945.

Dr. Mongan said he did not understand it that way. He spoke of the several extensions of the date when this law would become operative which had been granted by the Legislature. He said that this last extension ended in 1940.

The Secretary relayed a conversation which he had had with the secretary of the State Board of Registration in Medicine, in which the latter said that the schools had until 1945 to live up to whatever regulations the Approving Authority made. He further said that the secretary of the State Board of Registration in Medicine had promised to send to him certain information about the activities of the Approving Authority and that that communication was awaited.

Dr. Mongan spoke of the theory under which these extensions were granted and said in substance that the first extension was granted so as not to penalize any student who had in good faith entered a school whose standards might possibly be questioned. He moved, "That the President and Secretary take upon themselves to inquire from the Attorney General's office what, in the opinion of the Attorney General, is the interpretation of the law."

Dr. Ober announced that there was a motion before the house and that if Dr. Mongan's thought prevailed it would have to be offered as an amendment to the original motion. The Secretary said that it was his belief that the Attorney General would not give an opinion on a matter of law to a private organization such as the Society. These opinions are usually reserved for departments which are in the government. Dr. Mongan thought this might be so.

Dr. Norman A. Welch, Norfolk, said, and he asked Dr. O'Hara to correct him if he was wrong, that it was his understanding of the law that it is now effective for the scrutinizing of the education of students who entered these schools in September, 1941, and that these schools are to be under this scrutiny during the next four years, to deter-

mine the education which they give the entering classes that go in this year Dr O'Hara said that this was his understanding

The motion to accept the report was put by Dr Ober and was passed

Dr Mongan moved that the matter in question be given the attention of the President and Secretary with a view of enlightening the Council concerning what the situation is This motion was seconded by Dr Fitz and adopted on vote of the Council

#### APPOINTMENTS

Dr Ober said that in making the following appointments he had had the assistance of the Executive Committee He added that by this means he hoped to make better appointments than otherwise would be possible

Dr LeRoy A Schall, Middlesex South — chairman Auditing Committee

Dr John Rock, Norfolk — member Auditing Committee

Dr Reginald Fitz, Suffolk — chairman Committee on Postgraduate Instruction

Dr James C McCann Worcester — chairman Special Committee Concerned with Prepaid Medical Care Costs Insurance

Dr Elmer S Bagnall, Essex North, and Dr Peirce H Leavitt, Plymouth — members, Special Committee Concerned with Prepaid Medical Care Costs Insurance

Dr Daniel L Lynch Norfolk — member Committee on Industrial Health

Dr Walter G Phippen Essex South — consultant to the Joint Committee on Health Education of the State of Massachusetts

Representatives from the Massachusetts Medical Society to the Massachusetts Central Health Council

Dr Robert J Carpenter, Berkshire

Dr Francis P Denny, Norfolk

Dr George D Henderson, Hampden

Dr William D Kinney, Barnstable

Dr Erwin C Miller, Worcester

Dr Robert B Osgood, Suffolk

Dr Eugene W Beauchamp and Dr Stanley C Cox — councilors, Hampden

Dr John M Murphy — councilor, Hampshire

Dr William J Brickley and Dr Maurice Fremont Smith — councilors, Suffolk

Dr Frederic Hagler — supervising censor Hampden

Dr James B Bigelow — censor, Hampden

Dr Henry A Robinson and Dr Daniel J Inley — censors Norfolk South

It was moved, seconded and passed that the Secretary be instructed to cast one ballot confirm

ing these appointments The Secretary announced that this direction had been complied with

#### OTHER BUSINESS

Dr Ober then announced that the meeting was now open for any business that might legally come before it

The treasurer, Dr Butler, asked the Council for a special appropriation of \$125.00 to cover the expenses of the Executive Committee He offered this as a motion It was seconded by Dr Mongan and adopted by vote of the Council

There was much discussion about certain additions to the Committee on Public Relations Dr Bagnall moved that the vice president, president elect and secretary be added to the committee, that the president elect be authorized to serve as vice-chairman of the committee and that all three additional members be without authority to vote This motion was seconded and adopted on vote of the Council

Dr J Harper Blaisdell, Middlesex East, moved that the President appoint a committee of five, which shall consider necessary and desirable changes in the by laws and which shall report its recommendations in writing at the next meeting of the Council Dr Blaisdell said that the by laws need many changes He pointed to the section which provides for the election of a president elect and stated that, as this reads, the president elect serves for one day only He gave Dr Dutton credit for the initiative in this matter Dr Fitz seconded Dr Blaisdell's motion, and it was so ordered by vote of the Council

Dr MacLachlan discussed House Bill 460, and under the authority of the Middlesex East District Medical Society (September 17, 1941) offered the following motion

That the Committee on State and National Legislation be instructed to take any and all such action possible to modify amend and/or clarify the provisions of the Premarital Examination Law (House Bill 460)

It was seconded by a councilor Dr MacLachlan said that there were a great many members of the Society who do not like this law He added that apparently it had been approved by the Committee on State and National Legislation, although he was sure that the Society did not know of its approval He then proceeded to read from the law The motion was passed

There being no further business before the Council adjournment was ordered at 3:15 p m

MICHAEL A TIERIE, Secretary

## APPENDIX NO. 2

## REPORT OF THE EXECUTIVE COMMITTEE

The Executive Committee has had two meetings. The organization meeting, held on June 23, 1941, was presided over by the president of the Massachusetts Medical Society, Dr. Frank R. Ober. Dr. Edward P. Bagg, vice-president of the Massachusetts Medical Society, was elected vice-chairman of the committee. Dr. Michael A. Tighe served as secretary. Under the by-laws it was necessary that at the moment of organization, this committee should select by lot six men who would serve for three years, six who would serve for two years and six who would serve for one year. The selection so made is as follows:

## THREE YEARS

*Berkshire* John J Boland, Pittsfield  
*Franklin* Frederick J Barnard, Greenfield  
*Hampden* George L Steele, Springfield  
*Middlesex North* William M Collins, Lowell  
*Norfolk* Carl Bearse, Boston  
*Worcester North* John J Curley, Leominster

## TWO YEARS

*Barnstable* William D Kinney, Osterville  
*Bristol North* William H Allen, Mansfield  
*Bristol South* Edwin D Gardner, New Bedford  
*Essex North* Frank W Snow, Newburyport  
*Middlesex East* Kenneth L MacLachlan, Melrose  
*Plymouth* Pierce H Leavitt, Brockton

## ONE YEAR

*Essex South* Loring Grimes, Swampscott  
*Hampshire* Lucius B Pond, Easthampton  
*Middlesex South* Dwight O Hara, Waltham  
*Norfolk South* Daniel B Reardon, Quincy  
*Suffolk* Augustus Thorndike, Jr, Boston  
*Worcester* Ralph S Perkins, Worcester

It was voted by the Executive Committee to create the office of executive secretary. On nomination by the President, Mr Robert St B Boyd was elected to this office.

The second meeting of the Executive Committee was held on September 10, 1941. Out of that meeting have come certain recommendations which are herein presented to the Council of the Massachusetts Medical Society.

Hitherto the annual meeting of the Council has been held on the morning of the first day of the annual meeting. Occasionally the Council meeting has run well into the afternoon. This arrangement has deprived the members of the Council of the privilege of attending many of the scientific sessions of the annual meeting.

The Executive Committee, while taking notice of the self-sacrificing interest which the members of the Council bring to the purely business affairs of the Society, still recognizes the direction in which their chief interest lies. This committee, having in mind the importance of the annual meeting of the Council and believing that attendance at this meeting should penalize the members of the Council as little as possible, offers the following recommendations:

**Recommendation 1** The Executive Committee recommends that the Council of the Massachusetts Medical Society designate the first day of the annual meeting as the time of the annual meeting of the Society.

**Recommendation 2** The Executive Committee recommends that the Council of the Massachusetts Medical Society hold its annual meeting on the evening previous to the annual meeting of the Society.

The committee believes that adoption of these recommendations does not involve a breach of the bylaws. Under the bylaws, the Council has the right to name the time and place of the annual meeting of the Society. The only provision in the bylaws which has to do with the annual meeting of the Council is to the effect that this meeting shall be held on the day previous to the annual meeting of the Society.

It has come to the attention of the Executive Committee that serious thought is being given to the matter of the rehabilitation of those selectives who have been rejected because of remedial defects. The Executive Committee, through its secretary, has been approached in this

matter by Mr Curtis M Hilbard, director of the Committee on Health of the Massachusetts Committee on Public Safety. While this is not entirely a medical problem, it is to some extent. It would seem important that the Massachusetts Medical Society should participate, first, in the determination of the size of the problem and, secondly, in how best it can be solved.

**Recommendation 3** The Executive Committee recommends that the Council of the Massachusetts Medical Society authorize the appointment, by the President, of a committee of five, which committee shall be known as the Rehabilitation Committee.

There has been much discussion in the Executive Committee as to the number of years a foreign practitioner of medicine should be resident in Massachusetts before being permitted to take the examinations of the Massachusetts Board of Registration in Medicine. The Executive Committee is entirely familiar with the present regulation which requires that such practitioners shall be the possessors of first citizenship papers. While this committee knows that the Committee on State and National Legislation has already given thought to this matter, it nevertheless believes that this is a subject for further exploration.

**Recommendation 4** The Executive Committee recommends to the Council of the Massachusetts Medical Society that the Committee on State and National Legislation be instructed to study further the matter which has to do with the number of years a foreign practitioner of medicine should be resident in Massachusetts before being allowed to take the examinations of the Massachusetts Board of Registration in Medicine.

The Executive Committee has considered in detail and at great length a tentative set of bylaws under which it is proposed to set up a system of medical care costs insurance. These bylaws were presented to the Executive Committee by Dr James C McCann, chairman of the special committee of five. A copy of these bylaws accompanied the notice calling this meeting. They will later be presented to the Council through the report of the Committee on Public Relations. The Executive Committee commends these bylaws to a painstaking and earnest consideration.

It has also come to the attention of the Executive Committee that there is much confusion in the minds of many fellows of the Massachusetts Medical Society as to the proper interpretation of certain phraseology contained in Chapter V, Section 2, of the bylaws of the Massachusetts Medical Society.

The Executive Committee therefore submits the following resolution by means of which it seeks to have the Council interpret the language involved:

WHEREAS, The Massachusetts Medical Society is desirous that all skillful and ethical practitioners of medicine in Massachusetts shall be members of the Massachusetts Medical Society,

WHEREAS, Chapter V, Section 2, of the bylaws of the Massachusetts Medical Society provides the means by which practitioners in medicine in Massachusetts may become members of the Massachusetts Medical Society

WHEREAS, By the language involved in Chapter V, Section 2, of the bylaws of the Massachusetts Medical Society the Council of the Massachusetts Medical Society intends that it shall have accurate knowledge of the training, medical skill and ethical conduct of those

who seek admission to membership in the Massachusetts Medical Society;

WHEREAS, In the case of graduates of nonapproved schools, Chapter V, Section 2, of the by-laws of the Massachusetts Medical Society provides that the applicant for membership in the Massachusetts Medical Society shall have been in the practice of medicine for a minimum of five years;

WHEREAS, In establishing such a period of probation for graduates of nonapproved schools, the Council of the Massachusetts Medical Society intends that it shall have had opportunity to observe closely the medical skill and ethical conduct of such applicants; and

WHEREAS, In the case of most graduates of foreign medical schools who have been in the practice of medicine for five years in foreign countries, the Council of the Massachusetts Medical Society has no opportunity to know of the training or adequately observe the medical skill and ethical conduct of such medical practitioners; therefore, be it

RESOLVED, That the Council of the Massachusetts Medical Society interprets the phrase "who has practiced for a minimum of five years," as appearing in the by-laws of the Massachusetts Medical Society, Chapter V, Section 2 (b), to mean what is meant by the phrase, who has lawfully practiced for a minimum of five years in the United States; and be it further

RESOLVED, That the Council of the Massachusetts Medical Society shall be considered to have accurate knowledge of the medical training and medical skill of such graduates of foreign medical schools who have practiced medicine in foreign countries for five years and who are eminent in the profession of medicine and well known to the Council of the Massachusetts Medical Society for their scientific attainments, provided such practitioners shall have satisfied the Council of the Massachusetts Medical Society that their medical practice has been ethical according to the standards as set down in the *Code of Ethics* of the American Medical Association.

MICHAEL A. TIGHE, *Secretary*

#### APPENDIX NO. 3

##### REPORT OF THE COMMITTEE ON MEMBERSHIP

The committee recommends:

1. That the following named three fellows be allowed to retire under the provisions of Chapter I, Section 5, of the by-laws:

Collins, William J., Northampton  
Eldridge, David G., Milton  
Mason, Nathaniel R., Marblehead

2. That the following named three fellows be allowed to resign under the provisions of Chapter I, Section 7, of the by-laws:

Catinella, Paul J., Rochester, Minnesota  
Macomber, Donald, Boston  
Strong, Archibald M., New York City

3. That the dues of the following named two fellows be remitted under the provisions of Chapter I, Section 6, of the by-laws:

Ford, John F., Roslindale, 1941  
Shukle, R. M., Boston, 1938 and 1939

4. That the following named five fellows be allowed to change their membership from one district society to another without change of legal residence, under the provisions of Chapter III, Section 3, of the by-laws:

FROM ESSEX SOUTH TO MIDDLESEX EAST  
Ward, Joseph O., Saugus

FROM MIDDLESEX SOUTH TO SUFFOLK  
Brailey, Allen G., Newton Highlands

FROM NORFOLK TO SUFFOLK  
Auglem, Thomas J., Milton

FROM NORFOLK SOUTH TO SUFFOLK  
Williams, Robert H., Squantum

FROM SUFFOLK TO MIDDLESEX EAST  
Chisholm, Julian F., Jr., Boston

5. That the following named six fellows be recommended for readmission under the provisions of Chapter I, Section 10, of the by-laws:

Chayet, Jacob, Brookline  
Dushan, Sidney S., Mattapan  
Messer, Edward C., Dorchester  
Peterson, Reuben, Duxbury  
Pulsifer, Nathan, Lowell  
Sannella, Theodore, Boston

G. COLKET CANER, *Chairman*

#### APPENDIX NO. 4

##### REPORT OF THE COMMITTEE OF ARRANGEMENTS

At a meeting, as required by Chapter VII of the by-laws of the Society, the Committee of Arrangements, in co-operation with Dr. Ober, voted, after due deliberation, to hold the next annual meeting of the Society in Boston at the Hotel Statler on May 26 and 27, 1942. If this convention according to custom were to be held on the second Wednesday of June (June 10), there would be a conflict with the annual meeting of the American Medical Association in Atlantic City; this did occur in 1931. Pending your authorization, therefore, it was decided that there should be no such conflict.

The Committee of Arrangements endorses firmly the proposal of the Executive Committee, which you have approved this morning, that the next annual meeting of the Council be held in the evening preceding the first day of the annual meeting of the Society, according to present plans on the evening of May 25, 1942. Such a change would not only permit councilors' attendance at program functions which they cannot enjoy as it is, but also it would allow them to advance likewise the date of the annual business meeting of the Society by one day to the first day of the convention. Then the program of the second day could proceed without interruption.

Reservations have been made tentatively at the Hotel Statler, whose greater accommodations are sufficient for all our usual or anticipated demands and where a better attendance is more likely. Concerning other important details, like progress with the composition of the speakers' program, no satisfactory report can be presented at this time since such arrangements are so contingent on your decisions of today.

For future meetings it might be a time-saving measure for the Council to declare that it expects no conflict in

the dates of the two conventions and that any invitations from district societies to hold the annual convention outside Boston must be received by the Committee of Arrangements well before the annual meeting of the Council. Please consider these suggestions as a part of this report of the Committee of Arrangements but not as motions for action.

This report ends with the resolution

That the next annual meeting of the Massachusetts Medical Society be held at the Hotel Statler in Boston on May 26 and 27, 1942

WILLIAM T O'HARRIS *Chairman*

## APPENDIX NO 5

### REPORT OF THE COMMITTEE ON STATE AND NATIONAL LEGISLATION

**Organization** This committee was appointed at the annual meeting in 1940. There was a central organization of the following members: Henry C Marble, David L Lionberger, Brunard F Conley, Charles A Robinson and Earle M Chapman.

In each of the several districts a similar committee was appointed at their annual meetings, and during the past year of service, the following physicians have acted as chairmen of these committees: Dr D E Higgins, Dr P J Sullivan, Dr W M Stobbs, Dr E F Cody, Dr Edward Ganley, Dr C A Worthen, Dr H G Stetson, Dr W A R Chapin, Dr E E Thomas, Dr K L MacLachlan, Dr Michael A Tighe, Dr B F Conley, Dr E L Kickham, Dr J E Knowlton, Dr George A Moore, Dr E M Chapman, Dr L M Felton, Dr J V Gallagher, and Dr R F Bachmann.

Because of the geographical position of the central committee, it fell on this committee to attend most of the hearings at the State House, but at various times it was necessary to call in members of the other committees for assistance, and they all worked well in conjunction with us in carrying the legislative work of the Society into every corner of the State. It was because of this far flung organization and effective work that we were able to accomplish what we did.

The Society engages the services of a legislative reporting bureau which reports to us all bills that have been entered and, in many cases, furnishes us with type written copies of the bills even before they are printed. It so happened during the early part of 1941 that on certain occasions a bill went to hearing before a legislative committee even before that bill had been officially printed. From this it must be clear that it was difficult to keep up with the flow of hearings. As each bill was entered, it was assigned to one of the members of the central committee for study. He read it, and thereafter reported with his recommendations at a meeting of the central committee, at that time the policy that should be followed was worked out. Immediately after this was done the first legislative bulletin was published, which was sent to all the district legislative committees. Thereafter it was found that many bills had been entered that did not appear to be of interest to the Society because of the obscure title, and on several occasions it was not until a day or two before the bill was heard that we had knowledge of its existence, or were aware of the fact that it had medical implications. All this required hasty preparation and many telephone calls and hurried conferences.

After filing, each bill is assigned to a committee by the speaker of the House. The committee puts a date for

the hearing. There may be many other hearings on the same date before the same committee. It is the duty of the committee and the legislative counsel of the committee to be present at all these hearings and to furnish proper evidence in the form of speakers to present the case of the Society.

After the hearing, the petition is written into the form of a bill and is presented to either the House of Representatives or the Senate. If, however, the bill calls for the expenditure of public funds, it must further be heard before the Committee on Ways and Means before going to the floor of the House or Senate. Any of these committees may amend, alter, change or entirely rewrite the bill. After the bill has been acted on in one branch, it is then referred to the other, where substantially this same program is repeated, and even in the case of a relatively unimportant petition, it must be carefully and diligently followed from beginning to end. To accomplish all this is a full time job for at least one man, and a large part time job for a legislative counsel.

If you will refer to the legislative bulletin, you will note that the various bills fall into several classes:

**Medical education** This includes medical schools, medical training, requirements for practice, and control of matters of medical education. Into this class fall S 485, S 560, H 114, H 272, H 611, and H 1722. We might say that it has been the policy of the committee to do everything in our power to improve and to safeguard the laws governing the practice of medicine. The bill establishing the Approving Authority to regulate medical schools has been in force since January, 1941. Up to this date, we have been unable to obtain a report.

**Nurses and nursing education** The history of the effort by the Nurses Association to have a separate Board of Registration is long. However, the nurses' registration bill has been entirely rewritten from the form in which it was presented at first and has been passed through the Legislature and is now in force. In brief, there is a separate board of registration for nurses. There is, in addition, an advisory council with power to control matters of nurses' education and to approve hospitals having training schools. This further is expanded to include attendants. It is our feeling that this will be a satisfactory and useful bill.

**Hospitals** A bill was presented by the Massachusetts Hospital Association, which bill we were glad to approve, it gave the Department of Public Health authority to license general hospitals. This bill started as H 1232 and was rewritten as H 2528. In the closing days of the legislative session this bill was passed and signed by the Governor.

**Public health** The major item was the enactment of the Massachusetts Medical Society bill for the prepayment of medical care. This bill passed the Legislature, as nearly as I can determine, without a dissenting vote and is now a law.

Other bills were presented relative to premarital medical advice. H 460, providing for premarital examination by a qualified physician was passed and signed by the Governor on August 2. The annual anti-vaccination bill was presented and again given leave to withdraw. In general the committee sought to co-operate with the Department of Public Health in all constructive measures.

**Drugs and poisons** Several bills were presented by the Department of Public Health relative to food and drugs. In all of these we supported the department

An effort was made to restrict the sale of barbituric acid and its derivatives; this was not passed. A bill to limit the sale of pure ethyl alcohol was presented, but was defeated.

It is my considered opinion that the work of this committee in the future can be much simplified if many of these matters which we now have before us are considered and made part of a long-term policy of the Society. We should proceed to lay out a program of progressive public-health legislation that will embody most of the matters that have been here covered. It is further my opinion that this should be given to the Society long enough ahead so that it may have an opportunity to give the program careful study. I am entirely confident that any such long-range program would be welcomed by the Legislature. If the Medical Society offers such a progressive program, I am sure that it will forestall the filing of many time-consuming petitions.

HENRY C. MARBLE, *Chairman*

## APPENDIX NO. 6

### REPORT OF THE COMMITTEE ON PUBLIC RELATIONS

The Committee on Tax-Supported Medical Care, reporting through the Committee on Public Relations, is stimulating progress toward the setting up of district committees for improvement in the distribution of medical care in this field. The secretary of each district society and the delegates to the Committee on Public Relations are endeavoring to have the district committee authorized by the first meeting of the district society, thus carrying out the vote of the last Council meeting. Several local plans have been started on the initiative of organized medicine, and information regarding these is being distributed as fast as it becomes available.

The McCann Committee presents through the Committee on Public Relations the by-laws for a corporation to be known as the "Massachusetts Medical Service Corporation." These have been considered by the Committee on Public Relations, and it recommends their adoption as a basis for discussion, with the understanding that after constructive criticisms here and from other sources, they will be again presented to you for final approval before adoption. Rules, regulations and contracts with physicians and subscribers have not yet been prepared.

E. S. BAGNALL, *Secretary*

\* \* \*

### REPORT OF THE COMMITTEE ON PREPAID MEDICAL-COSTS INSURANCE

For your consideration, the committee is presenting by-laws, which represent the most vital step in establishing a corporation for prepaid medical service. Within a set of by-laws are established the essential characteristics of a corporation; furthermore, by-laws can guarantee or forfeit very valuable rights and powers with reference to the practice of medicine.

With our presentation today there has been distributed a printed form of the by-laws. Although it does not constitute a printed final, an unalterable form for you to act on, these by-laws indicate in principle the type of corporation that your committee believes conforms with the intent of the majority of the Council and the Massachusetts Medical Society.

As you know, several years ago the Council decided by a majority vote to embark on a program of prepaid

medical insurance. Under the able chairmanship of Dr. Thomas H. Lanman, this purpose was forwarded when an enabling act was signed by the Governor on May 22, 1941. The purposes behind your decision should necessarily be considered in a discussion of the character of any program on which we embark. Before going over the details of the by-laws, I wish, therefore, to give you the basic thoughts and the philosophy in the mind of your committee when it drew up the by-laws.

The purpose in establishing such a corporation is twofold. The first has reference to the public at large, particularly the low-income segment of the middle-class group. Owing to insecurity of work and the lack of fixity of income in our present industrial age, the members of the low-income group claim that medical costs often attain proportions that are difficult to meet. In attempting to meet this demand for relief, we think that there are two objectives to guide us. First, if we seek to help them ameliorate the cost of medical care it can be done on the widely established principle of insurance, which dilutes cost on the basis of distribution of risk over a large group; secondly, by budgeting and prepayment, we can make it possible to take care of unforeseen medical costs ahead of time. It is the opinion of your committee that you have not committed us to seek other ends, which would only act to complicate the program and jeopardize any chance for success. The second purpose is personal, but may be expressed in terms of enlightened self-interest: we openly seek to diminish the hazard of compulsory health insurance. The chances are that, if our program succeeds and is widely accepted by subscribers, we can ward off this threat. However, there are two important considerations. First, the proponents of compulsory insurance may urge that we have not and cannot enroll sufficient subscribers except by appeal to the principle of compulsion—they even threaten to apply this philosophy in the form of compulsory savings. The second point which may be a factor in failing to ward off compulsory insurance is the result of a demand for contributions from the employer and from the State in payment of the premiums. On this basis there may be a demand for participation by the State in the activities of the corporation. However, if we can enlarge adequately the subscription lists and the funds coming from subscribers, I think we shall find little difficulty in warding off compulsory insurance.

There is also another very important principle to keep in mind with reference to compulsory insurance, namely, that any legislative program which is to be established is usually based to a large extent on pre-existing conditions. Hence, if a compulsory-insurance program were worked out in the Legislature it would in all probability be based on our existing prepaid insurance corporation. In England, for example, the system is handled by the insurance carriers that were already underwriting the voluntary schemes. If by your initiative we establish a satisfactory program, or a relatively satisfactory one, we can assure to ourselves control over the purely medical aspects of the program. We shall have conserved to the physicians of the State certain rights and privileges inherent in medical practice, which we maintain belong to us. If a program of compulsion is unhappily imposed on us later, on the basis of established corporate practice, we can still probably save to ourselves these rights and privileges, and a satisfactory basis for practice.

Having reviewed this background, I now suggest that there are definite steps to be taken in succession to establish such a corporation on a sound basis. The first step, of course, is to procure an enabling act, which we

already have done. The second is the adoption of by laws that will establish the character of the corporation, and thus we now seek, the third is the preparation of rules and regulations, which must be based on established by laws. The fourth is a study of the actuarial background in Massachusetts, in which task we shall profit greatly by the experience of other states which have already embarked on similar programs, and the last step is the preparation and offering of specific contracts.

To proceed with the writing of rules and regulations, your committee must know the type of corporation that physicians will accept, so that subsequent steps may be referred to a basic pattern. That is why it is urgent for us to arrive at a decision on this matter of the bylaws, which will create the pattern. There are three fundamental concepts that must always be kept in mind when writing the bylaws of such a potentially powerful corporation, so that we may not do damage to our own legitimate self-interest. These concepts are as follows: first, we are embarking very definitely on a business venture of great magnitude; secondly, we do so on the basis of establishing a corporate structure; and thirdly, so far as medical practice is concerned, it is to be done on a contract basis. So we are embarking on extremely troublesome waters, which involve us widely in the corporate and contract practice of medicine.

With reference to the business aspect of this program we should look at it from the vantage point of its parallel to the business structures that surround us. Thus we may clearly visualize our rights as well as our obligations, and guard against missteps which would lose us certain privileges and rights that are identified with the practice of medicine.

Any business structure is looked at from the viewpoints, first, of promotion; secondly, of organization and management; and, thirdly, of finance. Certainly this program is one that is sponsored and promoted by the physicians. With reference to its organization and management, there is one basic principle that we must always keep in mind lest we be misled: namely, that the professional aspect of such a corporation transcends its administrative and monetary aspects. When an ordinary business corporation is established, the basic problems are administrative. In seeking the basic problems in our corporation, let us draw a parallel with workmen's compensation insurance in which the professional or medical aspects require 85 per cent of the time to run the program. If we compare a medical service organization, which is devoid of all the legal matters pertaining to liability, the value of services, cash benefits and so forth, with compensation insurance, which has all these features, certainly the medical or professional aspects of the former will loom even larger than those of the latter.

Then, too, I think we must insist that the contribution of the physician transcends the contribution represented by the premiums of the subscribers, which are only a benefit or claim for completion of the contract. The subscriber contribution is not so-called risk capital, any more than your premiums to a stock life insurance company represent risk capital or an ownership claim. We are contributing the body of knowledge possessed by the whole medical profession, and the acquisition and use of that knowledge and skill by the individual physician. This knowledge, skill and practice represent, we should insist, capital knowledge that is of major importance in the operation of any medical service corporation. Certainly our knowledge is patentable—consider insulin and viosterol, however, our ideals do not permit universal patenting, and our progress is a universal gift to mankind. If the patents

of a business corporation represent some of its most valued assets, certainly the knowledge and technical skill of the physician should represent a major capital interest in this corporation. So that as your committee tried to preform the character of this corporation, it seemed equitable to us that on the basis of business practices, the right of physicians to control judiciously this corporation should not be questioned.

With reference to the establishment of a corporate structure, we must give serious attention to the constitution of corporate structures and to the medicoeconomic significance of practicing medicine under a contract with a legal entity known as a corporation.

The corporation that we envision may be potentially a most powerful organization. If it should bring in a large proportion of the seven thousand resident physicians of Massachusetts if it should bring in somewhere around 50 per cent of the 4,000,000 of the residents of the State, and if it should bring in all the funds that are turned over at present in the distribution of medical services between these groups, it could be one of the most powerful corporate structures in Massachusetts.

The one most important thing to keep in mind is the question wherein will control of the corporation reside? By what means will the physicians maintain their proper control of this corporate structure? Let us turn to the common business corporation to sense just what we are doing, keeping ever before us the truism of corporate practice, namely, that wherein resides control of the board of directors, there resides control of the corporation.

Corporations are of two basic types, the profit corporation and the nonprofit corporation. Under the profit corporation there are three types so far as control of the board of directors is concerned. There is control by majority stock ownership, in which a sufficiently large block of stock is in the hands of one man or of a small limited group of men, so that he or they can dominate the board and the practices of the corporation. This power is achieved through the right to nominate and elect and to remove the board of directors. The directors are representatives of the stockholders who determine the practices of the corporation for the benefit of the stockholders. They are completely amenable to control by the owners or the majority stockholders.

Coming from a corporation in which there is this minority stock interest we come to a corporation in which there has been such dilution of stock ownership by wide sale that there are no blocks of shares sufficiently large to create a majority stock ownership. This results in minority stock control. Immediately one begins to see how dangerous such a development in corporate structure may be for the owners of the corporation. A minority block may be insufficient in size to control the conduct of the business by controlling the acts of the board of directors. Such a board may work its will as it pleases, even defying the demands of the owners. The classic example of such defiance is the Standard Oil Company of Indiana. Here the chairman of the board of directors, Colonel Stewart, defied John D. Rockefeller, Jr., representing the chief minority stock interest, in the conduct of the corporation, so that Mr. Rockefeller had to spend millions to procure proxies sufficient to enforce the will of the owners on the management. Herein we see the danger that comes when the affairs of the corporation are placed in the hands of a board of directors not completely subject to the will of the owners, or to the will of those who have rightful claims to priority in the corporation.

Next we come to what is called management control of a corporation, which is best exemplified by the American

can Telephone and Telegraph Company. I have a younger brother who is a general manager and vice-president of one of the subsidiaries of this corporation, and I know just how much attention would be paid to any representation to him or his associates by a stockholder in the matter of administering the corporation. The stockholder would be received with the greatest courtesy, but when he left the office the matter would be pigeonholed. The chief characteristic of this form of corporate structure is that absolute control is exercised by a board of directors; the stockholders are completely impotent because of dilution of their powers by the excessive distribution of stock. Thus the owners of a corporation can lose control of the corporate structure that they own and have created. This situation parallels our own, in the absence of a stock issuance by our corporation. We now see why we must procure control.

Moving to the nonprofit corporation, we enter the field in which our medical-service corporation will be chartered. In the usual philanthropic, nonprofit institution, there is no great concern over where control of the corporation resides, or what extent of control the owners of the corporation have over the board of directors. For instance, the Home for the Blind in Worcester has been endowed with funds and established, and there is little more to be done other than to conserve the funds and to carry out the corporate purpose of maintaining a home for the blind.

Next in the line of nonprofit corporations from which we can draw instruction is the Blue Cross. There are vital differences between the Blue Cross and what will be our corporation for medical service. The Blue Cross has been established as a sort of insurance go-between for the patient and the hospital corporation. The Blue Cross has no power over the individual corporate structure of hospitals; the individual hospital corporation is still in full control of its own destiny. The hospital directors are in no way controlled by the Blue Cross.

But when we move on to the formation of a medical-service corporation, a nonprofit corporation, we cannot afford to take the viewpoint that its setup is as innocuous as that of the Blue Cross. The physicians of the State, who are in complete control of the profession of medicine, are planning to place a large part of their practice under the control of a corporation by the medium of a contract. There is no stock ownership so that we cannot control this corporation through the medium of stock ownership. We have to adopt other measures of control if we are to protect our inalienable interests.

Those of us who have been interested in the philosophy of corporate structure in America know that in recent years two hundred corporations have achieved control of 50 per cent of the entire corporate wealth of the United States and control some 15 per cent of the employed workmen of America. I shall cite one authority on the growing separation of ownership in a corporation from control, so as to impress you with the importance of control—the statement of Justice Brandeis in the case of *Liggett versus Lee* (288, U. S. 517 [1933], p. 548):

Ownership has been separated from control; and this separation has removed many of the checks which formerly operated to curb the misuse of wealth and power. And as ownership of shares is continually becoming more dispersed, the power which formerly accompanied ownership is becoming increasingly concentrated within the hands of a few. The changes thereby wrought in the lives of the workers, of the owners, and of the general public are so fundamental and far-reaching as to lead these scholars to compare the evolving "corporate system" with the feudal system;

and to lead other men of insight and experience to assent that this "master institution of civilized life" is committing it to the rule of plutocracy.

The control that we should establish over the corporation ought to be based, first, on this background of principles and facts that we have just discussed; secondly, it should be governed by the principle that all distinctly professional matters should be kept in the hands of the physicians; thirdly, the organization should be so arranged that in the future such power over professional matters should not be allowed to get out of the hands of physicians; and fourthly, we should keep in mind the necessity of procuring an intelligent representation of the public in this program.

Turning now to the diagram or pattern of our corporation, there are three major subdivisions of the corporation: that division wherein we establish a voting membership; that wherein we establish a managing body or board of directors; and that wherein we create for the district societies the very highest degree of home rule by establishing units, which will carry out locally the purposes of the corporation.

In brief outline, we have established the Executive Committee of the Massachusetts Medical Society, composed of twenty-three members, as the voting members. This is the only point at which physicians, who are entitled to controlling powers, can enter this corporation, other than by comprising a majority of the directors. The latter has many undesirable aspects, which I shall discuss later. We first had all the members of the Council as voting members, but as we discussed the problem we thought that for the sake of functioning satisfactorily, it would be better to have a small group of physicians as voting members, who would be definite representatives of the Society as a whole, because we must visualize that once this corporation is established it will practically run itself. The Executive Committee will be more or less what you might call the watch-dog of the system, seeing that nothing which jeopardizes the rightful and proper interests of physicians takes place. This is the group in the corporation which has control of the corporation by virtue of the powers granted them in the by-laws: power to appoint directors; power to remove directors; sole power to change the by-laws, which perpetuate their powers; and power to review vital actions that will arise.

The number of the Board of Directors, the second group on the diagram, has been set at fifteen. One third shall be physicians; one third, as required by the enabling act, shall be subscribers; and the other third may be made up of prominent laymen. If this corporation assumes the proportions that we believe it well may, there are certainly going to be distinct problems of administration and of finance with which the directors must concern themselves expressly. Hence, we must have a setup that will allow us to call on suitable persons in the community to assist in carrying out these parts of the corporate responsibility. To return to the alternative proposition, if we were to seek to control the corporation by putting in a majority of physicians as directors, we should create a situation wherein we could not call on that powerful, intelligent body of citizens whom we need to assist us. Let us assume there is a board of fifteen directors. If a third, or five, are subscribers, and a majority, or eight, are physicians, one would not secure, we believe, in the two remaining appointments sufficient representation of those lay people from whom we need so much help. So in rejecting, as impracticable, control by a majority of physicians as directors, we have substituted what seemed to us to be a fair and effective setup, in which the physicians will have

unquestioned control of their own professional concerns. This is achieved by allocation of control over such questions to the Central Professional Service Committee, which is composed, with one exception, of physicians. We have delegated to them sole power to initiate action on vital medical matters. With reference to such matters, only these physician directors can initiate alteration of the rules and regulations, which will emanate from this body, the Council of the Massachusetts Medical Society. As the doctors are the producers and distributors of medical care, a board of directors should properly be our representatives. Since we are creating a board of directors with lay and subscriber members, we are justified in protecting our quasi-ownership rights by this indirect method, thus keep

Massachusetts Medical Society. That does not commit us one way or the other on the election of the directors, so we choose to elect all of them. If the subscribers find some way of nominating their representatives, certainly in view of our power to elect, this is acceptable. When I say our power I mean the Executive Committee's power to elect the directors, a majority of whom are acceptable to them. They have power to terminate directorship. This is nothing unusual in corporate practice, indeed, in all business corporations it is stated that the members may, with or without cause, terminate the tenure of office of any member of the board of directors.

This draft states definitely that amendments to the bylaws are in the hands of the members of the corpora

## MASSACHUSETTS MEDICAL SERVICE CORPORATION

### MASSACHUSETTS MEDICAL SOCIETY

- 1 Creates corporation
- 2 Controls it by direct elections through the voting members

### VOTING MEMBERS OF CORPORATION

(THE 23 MEMBERS OF THE EXECUTIVE COMMITTEE OF THE COUNCIL OF THE MASSACHUSETTS MEDICAL SOCIETY)

- 1 Elect Board of Directors
- 2 Terminate directorship
- 3 Change by laws
- 4 Receive notice of changes by the Central Professional Service Committee

### BOARD OF DIRECTORS

(5 PHYSICIANS 5 SUBSCRIBERS 5 UNSPECIFIED)

- 1 Supervises and controls administrative matters with
  - a Medical director and assistants
  - b Administrative Committee(?)
- 2 Supervises and controls financial matters with
  - a Administrative group
  - b Finance Committee(?)
- 3 Appoints Actuarial Research Committee (at least 3 members)
- 4 Appoints Central Professional Service Committee (5 members of whom chairman and 3 others must be physicians) this committee has sole power to initiate changes reporting them to the voting members on the following:
  - a Extent of medical benefits
  - b Basis of compensation
  - c Standards of medical care
  - d Discipline of physicians
  - e Qualifications of specialists
  - f Extension of income groups

### DISTRICT ADMINISTRATIVE UNITS

(MAJORITY PHYSICIANS CHAIRMAN PHYSICIANS ELECTED BY DISTRICT SOCIETIES)

- 1 District administrative committees
- 2 District professional service committees (all physicians)
  - a Have sole power of concurrent action with the Central Professional Service Committee
  - b Supervise locally the quality of medical care
  - c Discipline local physicians
  - d Determine qualifications and furnish lists of local specialists for the benefit of subscribers (optional)

ing vital medical matters in the hands of bona fide representatives of the medical profession.

In the local communities we have established district administrative units, the third section of the diagram. Each is composed of not more than nine individuals, of whom a majority must be physicians engaged in active practice. We have arranged for the chairman to be a physician, since any committee is apt to be strongly influenced by the chairman. Certainly we must guard this opportunity of protecting the medical aspect of local problems. Under the setup, there is a district administrative committee endowed with administrative powers only, and a professional service committee composed of physicians, which has complete control of all medical matters.

To go into more detail concerning the powers of these three segments of the corporation, the members of the Executive Committee of the Society (young members) are destined to control it. They have given to them the power to elect the board of directors. The enabling act states that a majority of directors shall be approved by the

union. That provision is based on accepted legal practice. We are doing some things a little differently from the usual practice, but certainly we are doing something different when we place the practice of medicine in the control of a corporation. This grants to us control of the elemental provision that any change in these vital matters shall be initiated by the physicians. It also preserves to the Massachusetts Medical Society control through its young membership, which has been vested in the Executive Committee of the Society.

The fourth provision is that the young members shall receive notice of changes contemplated by the Central Professional Service Committee. It is stated in the bylaws that the president of the Massachusetts Medical Society be notified, but I think it might be well to change the designation to the young members, who include the president of the Society, thus all the members would receive notice of any pending change. This whole group shall receive a thirty-days' notice of any change in the essential medical matters, passed on by the Central Professional

Service Committee. It is provided in the by-laws that any three members of the Executive Committee may call a meeting of the members so that if by mischance any questionable act has occurred or is contemplated by any group in power, a meeting of the members may be called to discuss that change. I think we have preserved to the physicians an adequate measure of control of the corporation, since the members have power to withdraw written approval of the majority of the directors, or even to terminate their tenure of office, at any time.

Coming now in detail to the Board of Directors, with reference to the provision for one-third subscribers, there is one fact which interested the group when we were discussing this set of by-laws—which, by the way, has been approved in principle by the Commissioner of Insurance. The counsel for the Commissioner pointed out to us that at one point in its existence the financial sheet of the Blue Cross was in such shape that, but for the wide subscribers' interest in the corporation, its activity might have been discontinued. So that in the early period of its life, our corporation should have a protective subscriber interest, which will help to tide us over the period when the financial status of the corporation will be subject to quite careful scrutiny by the Commissioner of Insurance.

With reference to the other third of the directors, as I have said, if this program develops successfully we shall need capable public-minded citizens in this corporation. The by-laws are drawn in quite general terms not committing the corporation to questions of what committees shall be formed. We believe we should permit the directors to meet and to organize themselves as they find the requirements of the situation demand. We should not tie them down. In the by-laws we have, in general terms, made it possible for them to establish such committees as they find necessary to run the corporation. We have not concerned ourselves in the by-laws with the problems of the medical director, because we cannot now discern the respective duties of the medical director and the Board of Directors. Their functions should not be strictly limited in the by-laws, and must, of course, be worked out with experience.

In the by-laws, however, we do commit the Board of Directors to establish two committees: the Actuarial Research Committee and the Central Professional Service Committee. We think that the Actuarial Research Committee should be established for very definite reasons. There is no sound actuarial basis for setting up such a program as this: it is purely experimental. In this connection, I quote from an address by Mr. W. A. Milliman, assistant actuary of the Equitable Society, speaking in New York City before the Actuary Society of America. He said, "Despite the enormous amount of effort that has gone into studies of the cost of insuring medical care, there is very little data on which an actuary could rely in calculating the costs of these benefits." I also have a report of the Committee on Economics of the Canadian Medical Association, which was made as far back as 1934; on the subject of actuarial experience, it states, "Sickness risks do not lend themselves to actuarial calculations."

Even though a capable board of directors might plan to appoint such a committee, we thought it best to require the appointment of such a committee immediately, since our whole welfare is at stake in this project. That would assure us a sound study of actuarial bases in so far as they can be made from the very beginning of the corporation's life.

The other provision of the by-laws binds the directors to establish the Central Professional Service Committee. There is also provision in the by-laws for delegating to this committee sole power to initiate all changes in the

rules and regulations concerning vital professional matters. This retains in the hands of the profession control of those matters that the English physicians at first lost under compulsory insurance, and then recovered only after years of bitter struggle.

While we studied the probable functioning of a medical-service corporation, we selected six functions (designated "a" to "f") of the Central Professional Service Committee as matters of vital medical importance over which physicians should be entitled to control as the quasi-owners of medical practice. So far as it is possible to designate "property rights" in a professional service, these functions seem to cover our property rights. Such rights have been defined as "control of access to the instruments of production." These functions infringe on the right of the individual physician to practice his profession; and they relate to changes of policy by the corporation which might jeopardize his security in such practice.

Let us consider the subheadings in detail. (a) *Extent of medical benefits.* From the experience of the Blue Cross we know that problems relating to how much x-ray examination, how much anesthesia and how much of any other special service shall be included in a sanely rounded program must arise. Only physicians are equipped to solve such problems. (b) *Basis of compensation.* This does not relate to how much shall be paid specifically for a certain service. It has reference to the fact that only physicians are qualified to determine what the proportionate return for an appendectomy as compared with a resection of the colon or the home treatment of pneumonia shall be. (c) *Standards of medical care.* This has always been the special province of the medical profession, and our corporation will be based on our ideal of ever-improving standards of medical care. (d) *Discipline of physicians.* This relates only to handling the small 2 or 5 per cent of the profession who welfare experience has revealed will intentionally abuse the corporation by overtreating, over-visiting and so forth. We simply believe that such discipline should never be the province of laymen, as it is in some foreign compulsory insurance schemes, but that physicians only should be allowed to judge practitioners of medicine in these matters. (e) *Qualification of specialists.* This concerns only allocation of authority. It assures us that if, as and when the Massachusetts Medical Society acts on this matter, then under our corporation the matter will be handled by properly accredited physicians and not by laymen. No action on this matter is entailed by acceptance of these by-laws. (f) *Extension of income groups.* The Council has already voted that any determination or extension of income groups privileged to receive benefits from the corporation shall be voted on by the Council. This action is safeguarded by this provision and other provisions in the by-laws.

In the local professional-service committees, the right to act with the Central Professional Service Committee on such of these headings as have important local significance has been established. These include the supervision of the local quality of medical care, the local discipline of offending physicians, and the local handling of the specialist problem, when the society shall have decided on a course of action.

I am briefly going through the by-laws to point out the sections that carry out the purposes we have in mind. Of the 350 lines in these by-laws, roughly 200 lines are concerned with purely legal matters, whereas only 150 lines are pertinent to vital medical aspects. I shall indicate these pertinent lines.

Article II, Section 1, establishes the members of the Executive Committee of the Massachusetts Medical Society

as the young members of the corporation. Section 4 gives power to three of the committee to call meetings whenever they believe that action should be taken.

Article III, Section 1, gives to the Board of Directors the necessary powers to manage the corporation, and it states the composition of the Board of Directors. Section 3 gives the members the voting control for the removal of directors if it is deemed necessary. That is one point where the Commissioner of Insurance has reserved a question. He has not yet committed himself, but he has reserved the right to question whether the phrase with cause should or should not be inserted, nothing more vital than that. As I have already said, most business corporations can remove directors with or without cause. Section 7 allows the Board of Directors to adopt rules and regulations subject to the conditions of Article IV. That simply means that any rules and regulations that are primarily established will not be modified if they relate to the vital medical matters unless initiated by the Central Professional Committee and reported by it to the Executive Committee of the Society (voting members). Section 9 establishes the general power of the directors to delegate power so far as they see fit to committees and officers, but subject to such regulations as may be adopted by the board and restricted by the provisions of the by laws.

Article IV, Section 1, is to be changed as follows: "There may be appointed such committees as the directors deem necessary, and there shall be appointed an actuarial research committee and a central professional service committee. This simplifies the problem of appointive power. Section 2 gives, so far as we could assure it, complete control in vital medical matters to the Central Professional Service Committee, and thus indirectly to the Massachusetts Medical Society through its chosen representatives. Section 3 specifies the fact that only in this committee shall action on these vital medical matters be initiated. Section 4 simply provides a means for setting up as far as a basis as could be established for handling disputes or, rather, abuses by physicians. It does not carry through the final action, which is determined by the enabling act, which requires that action shall go to a special committee consisting of the Commissioner of Insurance, the Commissioner of Public Health and the Attorney General. But by the provision of the by laws, many minor disputes may be quickly disposed of without loading busy public officials with the innumerable little problems that must necessarily arise. Sections 6 and 7 relate to the establishment of the Actuarial Research Committee, to which shall be submitted all questions relating to actuarial studies. Article V relates to purely legal matters, and any question there should be referred to a lawyer, nothing vitally affects the pattern of our corporation.

Article VI, Section 1, relates to the action of each district society, to which, if this program is going to succeed, such matters should eventually be referred. Section 4 designates a subordinate local professional service committee to act in an advisory manner in conjunction with the Central Professional Service Committee.

Article VIII makes it possible for us if we wish, and as the other states have found it advisable to do, to offer limited policies in addition to complete medical service policies. When the income level is established by the Council, people below that level can get complete medical service contracts, above that level people may buy a policy for which they will receive compensation from the corporation. But the limited contract in no way binds the physician in his charge to the patient, so that the present relation which exists between the physician and the patient continues to hold. By this means we make an effort

to reach the higher income group, taking care however, to impose certain restrictions, which do not obtain in the lower income group. As our approach to the lower income group depends on the good will of the upper income group, we win their support by a limited subscribers' contract. Section 5 is a general provision included so that, if at any time it is the will of the Council to permit certain charitable organizations, welfare boards or other groups to participate in the payment of premiums, this may be done without discussion or change in the by laws.

Under Article VII, Section 3 there is a phrase at the end that may be difficult to understand. I refer to, "He shall not have the right to refuse to accept a subscriber as a patient or to continue treatment of a subscriber for the sole reason that he is a subscriber." The only reason for the statement is that if we are going before the public with an appeal for subscriptions, they will insist that the subscriber have this protection. As our lawyer, Mr. Twomey, put it, if they are to join this corporation which is controlled by physicians, subscribers should be assured protection from discrimination in favor of those who are paying patients.

Article IX, Section 1, leaves the question of amendments or any changes in the by laws to a majority of the members of the corporation. The counsel for the Commissioner of Insurance asked us to change this to read "by a vote of 15 members." Our purpose is that the powers of the members cannot be altered by changes in the by laws other than those to which the members subscribe. The physicians cannot be displaced from voting membership, which gives them the powers indicated and hence, ultimately, control of the corporation.

We have presented the type of corporation embodied in the by laws to you, hoping that we have sensed the will of the majority of the Society. We ask you to consider these by laws from the viewpoint of acceptance or rejection, or from the viewpoint of modification. If your decision is that these be rejected, then we ask you to outline the type of corporation you want. We cannot proceed to the rules and regulations until the character of our corporation is determined, so that we can refer rules and regulations to some definite pattern.

We have outlined for you the pitfalls in creating a medical service corporation. We have presented a specific set of by laws that create a corporation which, we hope, will meet with your approval. In asking for action on these by laws, we suggest the necessity of committing yourselves to a specific type of corporation. In making your decision you are restricted in your choice to one of the small number of types of corporations that have appeared on the current scene. They are:

1. *Compulsory health insurance*, in which control of the corporation resides in a federal or state bureaucracy. This type of corporation we hope to avoid permanently.

2. *Lay group (nonparusan) corporation*, in which a group of disinterested laymen organizes a medical service program and, hence, controls the board of directors. It is only by their grace that a group of physicians can control the medical problems. By the same token, they can deny the physicians control over these matters.

3. *Consumer co-operative*, in which a group of non-producers controls the producers of medical service, insofar as they appoint and control the directors. As only 5 per cent of the members of a consumer's co-operative retain supervisory interest, this means that a small handful of nonproducers controls the producing group. They may delegate powers over medical matters

to a group of physicians, but they may easily withdraw this privilege, since they control the directors and, hence, the by-laws. This is a precarious basis on which to risk the security of one's self and family.

4. *Medically controlled corporation.* With proper arrangement for protection of the rights of the subscriber, this is the type of corporation to which the bulk of physicians subscribe. Control may be achieved directly by placing physicians in control of the board of directors. This has evident drawbacks, as has been indicated. The other alternative is to achieve control of the vital professional problems indirectly, as we have done, by empowering a subcommittee of physicians to initiate all action on such matters. This represents an even more complete control of these vital matters by physicians than is assured in the setup with physicians constituting a majority of the directors.

## APPENDIX NO. 7

### REPORT OF THE COMMITTEE ON POSTGRADUATE INSTRUCTION

Since the annual meeting, the committee has arranged a curriculum for the postgraduate extension courses for the academic year of 1941-1942; this has been sent to each district postgraduate chairman. Courses will start as soon as proper arrangements are completed.

Owing to a curtailment of governmental funds, the general courses will be financed by a registration fee of \$5.00 for each physician who takes the courses. If any district wishes a postgraduate extension course on venereal disease, this will be given free; the expense will be met jointly by governmental agencies and the Society.

The committee has co-operated with the other New England state medical societies in organizing the fourth New England Postgraduate Assembly, which will be given at Harvard University, October 29 and 30, 1941; announcement has been made in the *New England Journal of Medicine*, and programs have been mailed to all legally registered physicians in New England. Further reports on these activities will be made at subsequent meetings of the Council.

REGINALD FITZ, *Chairman*  
LEROY E. PARKINS, *Secretary*

## APPENDIX NO. 8

### REPORT OF THE COMMITTEE ON CONVALESCENT CARE

Since 1938 the Committee on Convalescent Care of the Hospital Council of Boston has been concerned with the adequacy of facilities for convalescent care and has made an investigation of private nursing homes within a reasonable radius of Boston.

On January 9, 1940, a meeting of hospital superintendents and medical social workers was called by the committee to discuss the findings in connection with visiting nursing homes and setting up the Nursing Home Information Bureau. It was found that more than 90 per cent of the patients in these nursing homes were chronic and aged, and the committee raised the question as to whether the needs of this group should not be studied. The committee was urged to turn its attention to a study of the

entire question of placement of patients in these nursing homes, both from the point of view of hospital administration and the medical social workers.

The committee therefore voted to secure a complete record of discharges from in-patient services referred to medical social service departments for aftercare for a six months' period, to obtain information as to the number of individuals involved, the types of care requested and the final disposition of each case.

The first half of the study covered the three months' period of March 18 through June 18, 1940, and the second period was from November 1, 1940, through January 31, 1941. A preliminary summary report of the findings follows. This summary report represents data presented for consideration to the Committee on Convalescent Care of the Hospital Council of Boston.

\* \* \*

### Hospitals Included in Study

One tax-supported and nineteen voluntary hospitals were asked to participate in this study and to fill out a card for each discharge referred to the medical social service department for some form of aftercare. Fifteen institutions returned cards for the study. The number of patients referred for aftercare in the individual hospitals ranged from 1 to 219. Five hospitals sent in no cards. This was due to the fact that they have no social service departments and that the hospitals were not requested to make provisions for aftercare.

### Number of Cases

It is interesting to note that there were fewer requests for aftercare during the second period of the study, that is, from November 1, 1940, through January 31, 1941, than from March 18 to June 18, 1940, the figures being 710 and 604, respectively.

### Sex, Racial, Religious and Age Incidences

One thousand three hundred and fourteen individuals were referred to the medical social service departments of the fifteen hospitals for the provision of some kind of aftercare.

Of these, 560 were males and 752 females (no report on 2); 1242 were white, 63 colored and 3 yellow (no report on 6); 453 were Protestants, 592 Catholics and 230 Jews (no report on 39); 58 were under eighteen years of age, 899 between nineteen and sixty-five and 317 were over sixty-six (no report on 40).

### Care Provided

*Own home.* Five hundred and fourteen patients returned to their homes or the homes of relatives. Of this group, 239 received care from a visiting nurse and 25 received care from a practical nurse or registered nurse or were assisted by having a special housekeeper placed in the home. Two hundred and fifty patients returned to their homes with no special nursing care.

*Institution or nursing home.* Of the total number of patients 768 had some provision made for aftercare away from home. The Committee on Convalescent Care was particularly interested in this group, the type of care required and the facilities that were used for care.

Three hundred and eighty-nine were listed as *convalescent*; 301 were between nineteen and sixty-five years of age (no report on 21). Fourteen received care in tax-supported institutions, 195 in voluntary agencies, 154 in private nursing homes and 20 in special hospitals and sanatoriums; 6 patients were listed as requiring convalescent care but no information was given as to where they were placed. Of those placed in private nursing homes, 18 stayed one week or less; 41 from one to two weeks,

43 from two to four weeks, and 28 over four weeks (no report on 24), 72 patients paid less than \$1500 a week.

Two hundred and eighty six patients required facilities for chronic care, 154 were between nineteen and sixty five years of age (no report on 13). One hundred and twelve were cared for in tax supported institutions, 30 in voluntary agencies, 122 in private nursing homes of whom 75 paid less than \$1500 a week (no report on 47) and 16 in special hospitals, there was no report on 6 patients.

Terminal care was provided for 93 patients of these 36 were between nineteen and sixty five years of age (no report on 2). Twenty one were cared for in tax supported institutions, 15 in voluntary agencies, and 47 in private nursing homes (no report on 10), 20 private patients paid less than \$1500 a week.

Thus we find that of the 768 patients for whom care was provided in an institution or nursing home, 389 or 50.7 per cent, were convalescent, 266, or 37.2 per cent were chronically ill and 93, or 12.1 per cent needed terminal care.

#### *Adequacy of Care*

A report on the adequacy of the care provided shows that in 1072 cases the arrangements made were considered satisfactory, 134 were unsatisfactory, 11 were questionable. 6 patients died before arrangements could be completed. 3 patients were still in the hospital at the time of the close of the study, and there was no report on 84 cases.

The reasons given for dissatisfaction varied. Among those listed were lack of medical supervision in the nursing home, patient needed more care than available, patient or family refused to accept recommended plan of care away from home, patient complained of care according to the Nursing Home Information Bureau, the home was not very good, but the family arranged for admission. Patient could not adapt to group care in public institution. Home conditions poor, patient emotionally restless in new group and missed frequency of doctor's attention received on ward, distance made it difficult for relatives to visit, no occupational therapy in nursing homes, atmosphere of chronic invalidism for convalescent patient.

#### *Diagnosis and Prognosis*

No attempt has been made at this time to analyze the diagnoses or prognoses of the cases referred for aftercare or to relate them to any age grouping or type of care recommended.

#### *Charges*

The hospitals were asked to indicate the amount paid for aftercare and who paid it, that is, the patient, the social service department or some other private agency. They were also asked to indicate whether the patient paid from public-relief funds. Attention is called to the fact that the privately owned nursing homes are run as a business and for this reason seldom admit a patient on a free basis, although in justice to them, it must be said that in some cases they have continued care on a free basis or for a small charge. Patients admitted to tax supported institutions are, for the most part, admitted without charge.

One hundred and nine patients were listed as receiving free care, 329 paid for their care, 189 received public funds, 132 had their care paid for in full or part by the social service department, 104 were aided by other voluntary agencies.

T DUCKETT JONES  
HENRY I. GALLUP

• • •

After nearly three years of study of the needs of convalescent patients and existing facilities for their care

it has been found that convalescent care merges into the care of the chronic patient and the latter into the problem of caring for the aged. The privately run nursing home is essentially a home for aged persons with their chronic ailments. It is not a solution to the problem of convalescent care except for patients who can pay the higher rates in the better homes.

This committee is concerned chiefly with providing new facilities for the convalescent patient discharged from the wards of hospitals belonging to the Hospital Council and from other agencies in Boston, for example, the Community Health Association.

As a result of the tabulations recently made by medical social workers, it has been found that although the problem of convalescent care is an acute one it is not so great numerically as had been anticipated. The committee is agreed that although the tabulations show that there is need for facilities for an equal number of chronic patients, who would require longer periods of care, it is the function of this committee to concentrate on a solution, first of the convalescent problem.

The committee also believes that there is more information to be secured from the study with relation to the chronic patient and that, when the convalescent question has been reasonably well solved, attention should be focused on the chronic problem. Further consideration of these problems will constitute the immediate deliberations of the committee.

T DUCKETT JONES  
HENRY I. GALLUP

#### APPENDIX NO 9

##### REPORT OF THE COMMITTEE APPOINTED TO SUPERVISE THE APPROPRIATION BY CONGRESS FOR THE CONSTRUCTION OF A NEW BUILDING TO HOUSE THE ARMY MEDICAL LIBRARY AND MUSEUM

Word has been received from the Surgeon General of the United States Army in regard to the present status of the projected Army Medical Library and Museum. Final clearance of the site has been approved by the National Capitol Park and Planning Commission. That commission and the Fine Arts Commission have approved the design of the building and its setting on the designated site. The building is to occupy a block directly across the street from the Senate Office Building and adjacent to the Library of Congress on Capitol Hill.

A bill for the purchase of the land authorizing \$1,000,000, was approved by the Bureau of the Budget, passed by the House of Representatives, approved by the Senate Military Affairs Committee and on August 15, 1941, was before the Senate itself. In addition, funds for architect's fees have already been authorized and a contract has been made with Eggers and Higgins, who are now engaged in the preparation of plans.

ROBERT B. OSGOOD  
BENJAMIN SPICTOR

#### APPENDIX NO 10

##### REPORT OF SPECIAL COMMITTEE TO EQUALIZE DISTRIBUTION AMONG PHYSICIANS OF MEDICAL SERVICE TO WPA EMPLOYEES

Each month since our last report, a member of our committee has visited the WPA office in Boston, checked the records of payments to physicians and discussed matters relating thereto with Mr. Burns, State Compensation Of-

ficer. Very little of a controversial nature has arisen. Perhaps this is in considerable part due to the marked decrease in the number of WPA employees, with a consequent reduction in the number of those injured. In August this year the average number carried on the WPA rolls was 37,622 employees; in contrast, in 1938 the number was 126,165. The years between 1938 and 1941 show a progressively consistent decline in the number of those employed.

While on figures, an error made in the copying of our last report should be corrected. In the last paragraph of that report, it should read as follows: "\$1,047,401 has been spent for the total care of the approximately 85,000 injured workmen." This means a little more than \$12.00 for each case treated. The WPA office feels that this figure compares favorably with the amount paid for compensation cases in this commonwealth, which is approximately \$23.00.

In our last report to the Council it was stated that the State Compensation Officer and the committee planned to make \$500.00 the top at which a physician's name would be removed from the list of available physicians. An advisory letter from the Commission in Washington resulted in a change in this figure, and it was made \$1000.00 instead of \$500.00. Since about June 1, then, the \$1000.00 top has been in operation. Orders went out to all WPA timekeepers that no injured workmen be referred to any physician who had received that amount, or more, in fees from this type of work since its inception. Exception was to be allowed if the injured party specifically requested his family physician.

Under the date of May 10, 1941, a new ruling was made by the Commission in Washington. It did not come to our attention until after the meeting of the Council in May. To quote from this ruling: "In *doubtful* cases injured employees may *not* indicate their personal preferences, and shall *not* be referred to physicians of their own choice. Where federal medical facilities are not available, doubtful cases shall be referred by the project timekeeper to specially qualified physicians duly licensed under the state law to engage without limitation in the practice of medicine and surgery." The Committee did not favor this ruling, but experience had been bad with free choice according to the Commission, and we were not successful in our attempt to have it reversed. It was not deemed wise to make an issue of it, especially as it would include but a very small proportion of the cases. No complaints have been received as yet, and this rule has been in effect for several months.

With such a sharp reduction in the WPA rolls, the work of this committee should noticeably decrease. Regular formal reports to the Council may be omitted unless matters of importance arise.

## APPENDIX NO. 11

### REPORT OF COMMITTEE FOR STUDY OF PRACTICE OF MEDICINE

Although this committee was appointed in the spring of 1941, its assignment is no new interest of the Massachusetts Medical Society. One hundred and sixty years ago our society was chartered, among other things, to examine candidates for the practice of physic and surgery

and to grant letters testimonial of the examination of such as were found skilled in their profession. The thoroughness with which this was carried out has been recalled recently by the publication in the *Journal* of an account of the examination of John Fleet in 1788.\* There were controversies in those days, too, but they were smoothed without great difficulty, and the Society continued to protect the people against "those who may ignorantly and wickedly administer medicine" until 1894, when Massachusetts adopted its medical practice act. The story of these first hundred and twelve years is told in Chapter IX of Dr. Burrage's *History of the Massachusetts Medical Society*. It is referred to here because it establishes the fact that the Massachusetts Medical Society has traditionally upheld the highest standards of medical education and practice, and suggests that it should continue to do so.

The highest standards of medical education and practice are no longer maintained in Massachusetts. Here are the plain facts. In 1940, Massachusetts registered as many graduates of unapproved schools as did all the other states of the Union combined. In 1940, Massachusetts registered more graduates of unapproved and foreign schools (for which we have no method of approval) than she did graduates of the approved schools, including diplomates of the National Board of Medical Examiners. The data for the following tabulation are taken from the compilations of the American Medical Association:†

STATUS	MASSACHUSETTS LICENSURE FOR 1940‡				TOTAL
	APPROVED SCHOOLS	NAT. BOARD MED. EX.	UNAPPROVED SCHOOLS	FOREIGN SCHOOLS	
Examined	110	0	303	223	636
Passed	101	113	125	112	451
Failed	9 (8%)	0	178 (59%)	111 (50%)	298 (47%)

‡This tabulation has been changed from that presented to the Council on October 1 by the addition of the figures for those registered through endorsement of National Board Examinations.

This lamentable state of affairs has come about because the Massachusetts medical practice laws are geared to the nineteenth rather than to the twentieth century. The Association of American Medical Colleges and the American Medical Association have been raising the standards of medical education now for many years. As the medical schools became graded and improved, most state licensing boards began to take an interest and to co-operate in the formulation of new legal requirements that embodied the same educational ideas. Whereas only five state licensing boards refused to recognize the low-grade schools in 1904, the number of such boards had risen to forty-six by 1925. The fact that Massachusetts, in 1941, continues to recognize them means that for fifteen years we have been absorbing the country's second-rate educational output. For those who have practiced medicine for twenty years or more in any part of the Commonwealth figures are not needed to establish this fact—indeed it is a notorious fact throughout the rest of the United States that we are beginning to feel the effect of allowing our state to be the dumping ground for poorly trained physicians and surgeons.

The responsibility for this state of affairs is not easily placed. There are half a dozen things which might or might not have been done in the past, and there are a dozen reasons why they were or were not attempted. The present status is that although we are still operating under what a member of our own state board has called an "out-of-date and clumsy medical practice act," we have a State Approving Authority, which we expect will be able in 1945 to separate out and refuse the privilege of examination to graduates of medical schools that are not in its

\*Fleet, J. A fiery ordeal. *New Eng. J. Med.* 224:1006-1014, 1941.

†Medical licensure statistics for 1940. *J. A. M. A.* 116:2021, 1941.

opinion living up to the present day standards of medical education. It would seem to be idle to develop controversies now, when we are hopefully awaiting the tardy operation of this state authority, which was designed for and may yet be found to supply the necessary relief. This authority has no easy task before it. Controversies within the profession cannot help it and may supply material for political resistance to the consummation of its effort. We should support it firmly to the end that it may establish itself as completely and satisfactorily in Massachusetts as other similar authorities are already established in other states. Such support, however, need in no way deter us from an advance consideration of what our course should be if this authority is forced to succumb to opposing minorities in 1945.

If, in 1945, we find that we are merely awakening from a dream and that, in spite of our efforts and opinions, the people of Massachusetts wish to leave their backdoor open to the poorly trained physicians of the entire world, there is no reason why we should continue to pretend that the standards of the Commonwealth are sufficient for membership in our society. To do so would be contrary to the past history of this society and of all reputable medical organizations. The trial of the American Medical Association in Washington at least determined that a medical society has every right to maintain high professional standards of membership.

Those who now come into the practice of medicine through the approved channels of medical education have been highly selected, not only as to their scholastic aptitudes (which is all that any examination can cover) but on personal grounds as well. This selection beginning in college and continuing through medical school, is an expensive process, and although it does not weed out all the undesirable elements it comes as close to that accomplishment as possible. This is recognized by the Council's annual approval of the list of medical schools and colleges prepared by the Committee on Medical Education and by Chapter V, Section 2 (a) of the by-laws which provides for the admission of the graduates of these medical schools and colleges into the Society. Under Chapter V, Section 2 (b), however, the by-laws provide the machinery for admitting graduates of schools *not* recognized by the Council. The propriety of this arrangement rests on the assumption that the Society is willing to admit to fellowship graduates of schools which it is unwilling to recognize. This is a good democratic assumption but if it is allowed to operate indefinitely, it encourages the schools concerned to continue their resistance to inspection and improvement, and cannot but discourage the embryonic State Approving Authority in the initial efforts of what we have admitted is a difficult task. If we believe and want the members of the State Approving Authority to believe, that the present standards of medical education

are worthy, fair and just we should consider whether our requirements for admission to fellowship should not be as unequivocal as those of the United States Army, Navy and Public Health Service or of the National Board of Medical Examiners—not to mention most of the other states in the Union, that is, whether we have been too freely invoking Section 2 (b) under Chapter V of the by-laws.

This question is brought up now because it suggests a possible concrete step to be taken some few years hence. Consequences which might reasonably be expected to follow such a step may now be outlined. The better hospitals of Massachusetts would doubtless continue to require membership in the Massachusetts Medical Society as a qualification for staff membership. Their standards would thus be supported and gradually raised, and the medicine and surgery practiced within their walls would continue to improve. The nonconforming type of hospital on the other hand would be more conspicuously placed as an institution of lower standards. This would tend to concentrate the responsibility for the practice of good surgery even more emphatically where it already rests—in the hands of the hospitals. It is the opinion of this committee that the responsibility for the practice of surgery belongs in the hands of the hospitals, and that practical regulation can best be approached through registration or supervision of these institutions. It so happens that current legislation has been enacted charging the State Department of Public Health with responsibility for the licensing of hospitals and for setting standards for hospital equipment, records and so forth. The committee therefore recommends that the Massachusetts Medical Society heartily co-operate with the Department of Public Health in meeting this responsibility.

In summary. The standards of medical practice in the Commonwealth of Massachusetts are low. An attempt is being made in good faith to raise them through the establishment of the State Approving Authority. Controversies among those who are actively supporting this attempt are embarrassing and should be avoided. If the authority is obstructed in bringing about a higher standard of medical practice in Massachusetts, this society need no longer invoke Chapter V, Section 2 (b) of its by-laws, and may thus return to its traditional policy of supporting the highest standards of medical education and practice. This is a decision for 1944. Whether or not such a policy on the part of the Society becomes desirable at that time, an opportunity to co-operate with the State Department of Public Health in its licensing of hospitals is now at hand. The committee recommends that this opportunity be seized as an immediate step toward improving the practice of medicine and surgery within the Commonwealth.

DWIGHT O'HARA, *Chairman*

## MEDICAL PROGRESS

### METABOLIC FACTORS IN THE CAUSE AND CONTROL OF DENTAL CARIES

ALLAN M. BUTLER, M.D.\*

BOSTON

IN 1931, Hanke<sup>1</sup> wrote, "The literature pertaining to dental pathology is a chaos of facts and fiction (the latter being the outcome of a hyper-enthusiastic championship of a fixed idea) . . . ." In 1933, Howe and his associates<sup>2</sup> stated:

In the past few years, several reports have been made of the arrest of caries through dietary changes in various children's institutions in this country and in England. The preliminary findings of a recent survey carried on at Forsyth Dental Infirmary indicate that results similar to those reported from the institutional studies may be secured by the practitioner who has a working knowledge of nutrition.

This statement and the careful work of Zilva and Wells,<sup>3</sup> Howe,<sup>4</sup> McCollum and his co-workers,<sup>5,6</sup> Höjer,<sup>7</sup> Wolbach and Howe,<sup>8</sup> Mellanby,<sup>9</sup> Boyle and his associates<sup>10-12</sup> and others on the striking specific effects of vitamins A, C and D on the teeth of experimental animals suggested that the studies of subsequent years might provide objective information that would turn the chaos in the older literature on dental caries into an orderly sequence of established and generally accepted facts.

In 1939, The American Dental Association<sup>13</sup> published a book entitled *Dental Caries: Findings and conclusions on its causes and control*. The one hundred and ninety-five summaries presented therein by observers and investigators in twenty-five countries provide a relatively up-to-date cross-section of the dental profession's opinions on the etiology of "the most prevalent of all diseases." The report deserves careful study, because it depicts dental opinion in 1939 as compiled by the American Dental Association. I believe that it can be visualized without gross misrepresentation by presenting isolated but not distorted quotations from this authoritative source.

#### DIET IN GENERAL

There is no evidence that caries is produced by malnutrition or may be prevented by adequate diets.

Dental caries arise from metabolic disturbances which can be avoided or corrected through the use of diets high in all recognized nutritional essentials.

All articles in this series will be published in book form: the current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

\*Assistant professor of pediatrics, Harvard Medical School, and associate visiting physician, Infants' and Children's hospitals.

The author has not observed any favorable results on the progress of caries from changes in diet including additions of calcium, phosphorus and vitamins.

#### "CIVILIZED DIETARY"

The ultimate causes of caries reside in refinements of civilization and resulting changes of diet. To prevent caries the diet should be "natural" and rich in vitamins and minerals.

There is no basis for the view, frequently held, that freedom from caries in a primitive people is due to nutritional superiority of "natural" as compared with "civilized" diets.

#### CARBOHYDRATE IN DIET

Sugar or starch has not been observed to favor caries, unless use of either materially diminishes the amounts of ingested protective foods.

Active caries was induced in children by increasing the sugar intake while they were receiving a diet that nutritionally was adequate.

Amount of carbohydrate in the food is not [an] important [factor], provided all essentials are included in the diet.

#### ORAL BACTERIAL FLORA

No consistent relationship has been found between . . . state of mouth hygiene and activity of caries.

The most constant differential between caries-free and caries-susceptible persons . . . is that of relative number of *L. acidophilus* organisms in the mouth.

Studies of mouth flora have shown that children, after definite arrest of extensive caries . . . , may show high counts of acid-producing bacteria, especially *B. acidophilus*.

#### COMPOSITION OF SALIVA

Chemical analysis of saliva has revealed no correlation with activity or inactivity of caries.

Three factors cause susceptibility to dental caries: . . . (3) lack of sufficient phosphate in saliva to prevent solution of teeth salts by acid under bacterial plaques.

No correlation has been demonstrated between amounts of salivary calcium, phosphorus, chlorides, pH, CO<sub>2</sub>-capacity, total alkalinity, total solids or ash and activity of caries.

#### ACID-BASE BALANCE

The extent of excess of basic over acid metabolic end-products of the diet is unimportant in relation to caries.

The two most important relationships in caries prevention are the acid/base and calcium/phosphorus balances in the body.

No relationship has been demonstrated between intake of calcium, phosphorus or acid-base dietary values and activity of caries.

## CALCIUM AND PHOSPHORUS BALANCES

Retention levels of calcium, phosphorus and nitrogen are not correlated with presence or absence of caries.

Increased retention of calcium favors caries prevention.

There is no proof that addition of milk to ordinary devitalized diet prevents or cures dental caries.

With increased Ca intake [as in milk] there is a decreased tendency to caries.

The phosphorus deficiency theory accounts for . . . caries of pregnancy.

Pregnancy does not cause caries.

## HARDNESS OR CALCIUM CONTENT OF WATER

Calcium laden drinking water does not prevent caries.

There is an inverse relationship between drinking water hardness and caries incidence [that is, hard water does prevent caries].

## VITAMINS

Caries arises independently of the amount of vitamin C in the diet.

The dietary factors of chief importance to calcified dental tissues are vitamin D and A and mineral salts.

Addition of calcium and cod liver oil . . . to the diet of a caries susceptible does not reduce the disease.

It is interesting to note that in the general analysis of the findings and conclusions of this book no mention is made of vitamin C.

Naturally, this consolidation of contradictory statements places the conflict of opinion very much in the foreground. On the other hand, the limitation of the quotations to less than one third the contradictory opinions encountered in reading the report indicates that the conflict has not been exaggerated. If the picture is distorted, it is because it includes none of the details that distinguish the controlled experimental evidence obtained by sincere investigators from the theory of pseudoscientific enthusiasts. But the book itself includes no such details in the three pages of introduction or the one hundred and seventy pages of summaries or the fifteen pages of analysis of the findings and conclusions. However, at least three summaries, perhaps best described as fantastic theoretical verbiage, are not only included but also given the importance of being referred to in the analysis of the findings and conclusions. A more recent article by Fleisch<sup>14</sup> extends the theorizing about dental caries to the significance of the vitamin B factors but fails to present any definite facts concerning the role of these substances in the cause or control of caries.

Although Mellanby's experiments on dogs led her to emphasize the importance of vitamin D, calcium and phosphorus in the proper structural development of teeth in dogs, she<sup>15</sup> remarked: "There is as yet little direct evidence of the effect of diet on tooth structure in man. . . . However, a small amount of data suggests that good structure

of the teeth in man is obtained by following the same principles of diet which result in good teeth in dogs." Toverud and Toverud,<sup>16</sup> from experiments on dogs, concluded that a diet deficient in calcium, phosphorus and vitamin D during pregnancy and lactation predisposed the offspring to rickets and dental caries. They did not hesitate to correlate enamel hypoplasia and caries. Rosebury and Foley<sup>17</sup> reported that diets deficient in calcium and vitamin D had no deleterious effect on rats during pregnancy and lactation or on their young. Boyle and Bessey<sup>11</sup> stated that the carious processes in the guinea pig do not appear to be associated with defective tooth structure or with dietary deficiencies of vitamins A and C.

Young,<sup>18</sup> from studies with Mellanby on a group of children in Birmingham, believed that there was a significant association between tooth structure and initial caries and spread of caries, and that the ingestion of vitamin D during the period of tooth development before and after tooth eruption diminished the incidence of enamel and dentin hypoplasia and caries. Previously, Hess and Abramson,<sup>19</sup> in reporting studies on a group of institutionalized children, expressed a similar opinion concerning the role of vitamin D, although they called attention to the fact that the permanent incisors, which calcified during the rachitic period, were rarely carious, whereas the second permanent molars, which calcified after the rachitic age, were frequently carious. They further expressed the belief that lack of vitamin B, C or A did not play a significant role in caries. Fish<sup>20</sup> also called attention to the lack of correlation between teeth developed during the rachitic period and teeth having caries. In a recent paper, Boyd,<sup>21</sup> although emphasizing the value of vitamin D, arrived at the following somewhat indefinite conclusion, "The child with active caries must be considered to have a disturbance of metabolism, and this can be corrected most effectively through enrichment of the diet so that it will favor an optimum state of nutrition." Hess, Lewis and Roman<sup>22</sup> and Kronfeld and Schour<sup>23</sup> demonstrated that postnatal nutrition from birth to ten years of age is usually far more important to calcification of teeth than prenatal nutrition is. On the other hand, Toverud and Toverud<sup>16</sup> made much of the effect of prenatal nutrition on the first permanent molars as well as on the deciduous teeth. However, much of their evidence was based on experiments with dogs in which the conditions were extreme. Rare cases of the effect of extreme conditions of prenatal nutrition in man are provided by the structural defects in the deciduous teeth of infants with fetal rickets.<sup>24</sup>

As an explanation of why the hope of more specific knowledge from dental studies has not been fulfilled, certain considerations seem of interest. First, experimentation in this field is recent. Prior to 1920, metabolic research was largely concerned with total energy metabolism or total maintenance requirements and, therefore, did not provide the knowledge and technics applicable to the study of dental physiology. It was only when the establishment and cure of vitamin A, C and D deficiencies in experimental animals became susceptible of accurate control ten to twenty years ago that experiments on mineral metabolism were controlled and that experiments carried out by the investigators mentioned above<sup>3-12</sup> provided accurate information on the effect of vitamins A, C and D on the growth and development of teeth in animals. Secondly, warnings by careful investigators that conclusions concerning the relatively slow-growing or static teeth of human beings could not be drawn too readily from experiments on the rapidly or constantly growing teeth of animals seem to have been ignored by many. Thirdly, the application of this experimental knowledge to the problem of human caries, as indicated by the dental literature, was undertaken largely through studies of two types. One attempted to determine the effect of particular factors on groups of relatively healthy people; in such studies, extreme enough conditions were rarely established to assure predominance of the factor in question. The other embraced surveys of racial groups living under different conditions and consuming different diets. Here, too, control of the various factors in question was extremely difficult. Finally, the tendency to separate dental from medical clinics resulted in relatively few studies on the almost ideal ready-made extreme experimental conditions provided by sick patients in medical clinics. For this or some other reason, much of the very definitive information that has resulted from observations on such patients seems to have received little emphasis. A summary of such information follows.

Albright and his co-workers,<sup>25, 26</sup> Stafne and Austin<sup>27</sup> and Strock<sup>28</sup> have amply demonstrated that patients suffering from the extreme skeletal demineralization of hyperparathyroidism usually show no demineralization of the teeth or increased caries, although isolated cases of caries in such patients may be observed.<sup>29</sup> Maxwell and Miles<sup>30</sup> noted that severe osteomalacia in Chinese women did not result in caries, even though the teeth might fall out. Taylor and Day<sup>31</sup> likewise observed that women in the district of Punjab, India, — suffering from deficient diets, frequent pregnancies, long-continued breast feedings, chronic osteomalacia, tetany and deformities — usually had

nearly perfect teeth. Smyth and Goldman<sup>32</sup> observed good teeth in a fourteen-year-old boy with renal insufficiency who had suffered for over a year from the skeletal demineralization of renal rickets. At the Children's Hospital, good teeth have been observed in patients who have had renal rickets for a year or more and who at the time of examination were shown to have marked acidosis, low serum calcium, marked resorption of the supporting alveolar bone, absent lamina dura and generalized skeletal demineralization. Whether the demineralization in these renal cases resulted from the chronic acidosis or the secondary hyperparathyroidism is of no concern. But the fact that patients with chronic renal disease, osteomalacia or osteitis fibrosa generalisata can have extreme skeletal demineralization that does not affect the teeth suggests how little likelihood there is that the teeth are affected by such minor alterations in calcium and phosphorus or acid-base balances as those produced in the group type of experiments on relatively healthy persons.

As early as 1906, Erdheim<sup>33</sup> noted in rats that layers of dentin laid down while the rat was in the hypoparathyroid state failed to be calcified. Albright and Erdheim, in unpublished experiments, later showed that this acalcification of the dentin could be rectified by the injection of parathyroid extract into the rats. Albright and Strock<sup>34</sup> observed that the teeth of children who had developed hypoparathyroidism during adolescence failed to mature after the time of the onset of the disease. The experimental work from the laboratories of Schour<sup>35</sup> and Ziskin<sup>36</sup> confirms these findings. The delayed eruption and maturation of teeth in cretinism is well known. Ziskin and Applebaum,<sup>37</sup> in studying thyroidectomized rhesus monkeys observed both a delay in rate of dentin growth and an alteration in the quality of dentin calcification. Rony<sup>38</sup> reported marked delay in the shedding of deciduous teeth and in the eruption of permanent teeth in a patient with hypopituitarism. The marked rarefaction and fibrosis of alveolar bone with disappearance of lamina dura, resorption of tooth roots and hypercementosis that may occur in Paget's disease do not result in caries.<sup>27, 39-41</sup>

The foregoing evidence for the stability of the structure of the adult tooth in the presence of metabolic disturbances suggests, in spite of the popular belief to the contrary, that the drain on the calcium and phosphorus stores during pregnancy and lactation does not result in the demineralization of the teeth of women at such times. Eaton<sup>42</sup> concluded that any increase in caries during pregnancy was due to laxity in oral

care and not to pregnancy per se Ziskin and Hotelling<sup>43</sup> stated that "pregnancy is not a cause of dental caries" and that "some factors operating during pregnancy actually prevent tooth decay to a significant extent" Weisberger,<sup>44</sup> in studying a larger group of women during pregnancy and lactation at the Boston Lying in Hospital and Harvard Dental School, did not observe any increased incidence of caries Ziskin, Blackberg and Stout<sup>45</sup> described a gingivitis during pregnancy characterized by an epithelial hyperplasia that may well have been associated with some endocrine disturbance accompanying pregnancy Ziskin<sup>46, 47</sup> has discussed the possible role of endocrine disturbances in hypertrophic and desquamative gingival conditions not associated with pregnancy. His implications concerning the beneficial effects of hormonal therapy need confirmation and obviously may not be applicable during pregnancy

Bloch,<sup>48</sup> after studying the teeth of children who had manifest signs of vitamin A deficiency in infancy, concluded "In man, deficiency in vitamin A has no specific injurious effect on the formation and calcification of the teeth A disposition to dental caries, therefore, cannot be due to deficiency in vitamin A in infancy" Hess and Abramson<sup>14</sup> expressed a similar opinion Boyle<sup>49</sup> examined the tooth germ of a three and a half month old infant who by post mortem examination was found to have congenital syphilis and the generalized epithelial changes of vitamin A deficiency Ruling out the effects of syphilis, Boyle concluded that vitamin A deficiency may result in a hypoplasia characterized by atrophy of the enamel organ, with replacement of the enamel-forming cells by squamous epithelium and cessation of enamel formation and by defectively calcified dentin

Westin,<sup>50</sup> from studies of the scorbutic changes in the teeth and jaws of man, concluded that, although such changes were analogous to those in the guinea pig, none of his findings indicated that scurvy had any decisive effect on the formation of dental caries All his adult men with scurvy were practically free of caries Hess and Abramson<sup>19</sup> reported the same experience with children who had had infantile scurvy Boyle<sup>1</sup> studied the germs of the permanent and deciduous teeth in two cases of acute scurvy in infants eight and eleven months of age Each tooth germ was essentially normal Such minor changes as were found in several tooth germs of the younger child were in marked contrast to the striking lesions in the constantly growing incisors of scorbutic guinea pigs In a later paper, Boyle<sup>10</sup> remarked that, "from the evidence at

present available, dental caries in man and in the guinea pig does not appear to be due to a deficiency of ascorbic acid in the diet" He also stated that the clinical reports of Aschoff and Koch<sup>52</sup> and of Westin<sup>53</sup> suggest an immunity rather than a susceptibility to caries in ascorbic acid deficiency Crandon, Lund and Dill,<sup>54</sup> in their excellent study of acute experimental human scurvy, observed no changes in the teeth of a person who had been on an ascorbic acid free diet for six months and had definite manifestations of scurvy They did, however, observe a small hemorrhage at one gingival margin and interruptions of the lamina dura as visualized in roentgenograms Boyle, Bessey and Wolbach<sup>55</sup> observed in human beings on diets deficient in ascorbic acid a diffuse alveolar bone atrophy type of periodontal disease similar to the changes that Gottlieb<sup>56</sup> described in pyorrhea Howe<sup>4</sup> had previously noted that the dental effect of scorbutic diets on guinea pigs "more closely simulates pyorrhea than does any such condition produced experimentally"

Eliot, Souther, Anderson and Arnim,<sup>57</sup> in a study of children known to have had infantile rickets, observed a definite direct relation between hypoplastic defects of the enamel of permanent teeth and rickets but only a questionable relation between caries and rickets Hess and Abramson<sup>19</sup> reported a higher incidence of caries in a small group of children who had had rickets than in a control group On the other hand, they observed that a group of colored children who had had rickets had a lower incidence than white children with no ricketic history Shelling and Anderson<sup>58</sup> found that the incidence of dental caries in the deciduous teeth of a group of children who had had rickets during infancy was not greater than that of those who had been given vitamin D and had not had rickets Enamel hypoplasia was found oftener in the deciduous and permanent teeth of the post-ricketic group They concluded that their findings did not indicate a protective effect of vitamin D against caries in deciduous teeth or a relation between rickets and dental caries or between hypoplasia and caries Taylor and Day<sup>9</sup> found that children born of mothers with osteomalacia and reared on diets deficient in calcium and phosphorus and with a past history of infantile rickets had teeth with little or no hypoplasia or caries However, Toverud and Toverud<sup>16</sup> and Wolfe<sup>4</sup> have shown that gross hypoplasia of deciduous teeth may occur in such children Hjarne<sup>60</sup> reported a high incidence of hypoplasia in children who had had infantile tetany Rony<sup>38</sup> has suggested that the

presence of hypoplasia following rickets depends on the persistence of a low serum calcium concentration at some time during the period of tooth development. Hess and Abramson<sup>19</sup> expressed a similar opinion. Experience at the Children's Hospital with a group of children suffering from resistant rickets suggests a correlation between the degree of hypoplasia and caries and the past history of tetany and poor skeletal mineralization during the period of tooth maturation. Similarly, a child who, following the removal of a large section of small intestine, suffered from the age of two to six years with diarrhea, poor skeletal mineralization and tetany had marked hypoplasia and caries. Albright and Strock's<sup>24</sup> observation that the hypocalcemia of children with hyperparathyroidism affected the calcification of teeth indicates that in the absence of osteoporosis a low serum calcium concentration may result in faulty development of teeth. Because studies of teeth in hypoparathyroid tetany have dealt with patients older than those with infantile tetany, involvement of the crowns of the teeth to any great extent has not been noted.

Thus, in spite of the persistence of contradictions concerning the cause and control of dental caries in man, the experimental evidence and the clinical findings suggest the following:

Dietary deficiencies at the period when teeth are being laid down may cause hypoplastic defects in infancy and childhood that persist thereafter. The slow growth and prolonged period of calcification of human teeth renders them less susceptible to periodic deficiencies and metabolic disturbances than the rapidly growing teeth of experimental animals. Static, fully developed human teeth are practically immune to demineralization, whereas the constantly growing teeth of animals remain vulnerable to metabolic defects. Much of the contradiction in the literature on dental caries in man derives from unwarranted deductions from animal experiments and from the fact that many studies on man have involved experiments that, in the light of present knowledge, could hardly yield other than inconclusive results. The relation between enamel hypoplasia and dental caries needs further definition. No specific dietary factor or metabolic condition has been proved to cause or control dental caries in the fully developed human tooth.

### CASE 27451

#### PRESENTATION OF CASE

A sixty-eight-year-old housewife was admitted to the hospital because of vomiting and diarrhea.

She was apparently in good health until about seven weeks before entry, when she was seized with cramping pains in the left lower abdomen, associated with distention. After a short time, she began to have from six to eight watery, mucoid, blood-free stools a day. She also had spells of vomiting, always preceded by nausea. The vomitus was copious, fluid, green and free of blood. The combined attacks of abdominal cramps, diarrhea, distention, nausea and vomiting tended to be intermittent, with periods of constipation and freedom from pain, nausea and vomiting. After several weeks, there appeared a constant, gnawing pain in the left upper quadrant of the abdomen, which was relieved by morphine given by a local physician. According to the patient, this medication precipitated headaches and visual disturbances, which accompanied her acute episodes of cramps and vomiting. Her appetite became poor, and during the illness she lost about 45 pounds in weight. She became progressively weaker, until she was unable to walk across a room without support. In addition, there was a feeling that food would occasionally stick in her throat, approximately at the level of the junction of neck and chest. There was also cough, productive of yellow, mucopurulent sputum. At no time in the illness was there chest pain, hemoptysis or jaundice. Two weeks before entry, a physician removed a rectal polyp.

The patient had long experienced nocturia. Four years before her last illness, she felt weak and was treated medically in a local hospital, with a diagnosis of "Bright's disease." The family history was not significant.

Two days before admission, the patient entered another hospital, where she was found to be chronically ill and wasted. The eyes were sunken, and there was a scaling, red eruption over the nose and malar prominences. The skin was generally loose and flabby, and there was pitting edema over the sacrum and in both ankles. There was a

small nodule in the thyroid gland, both lobes of which were palpable. The chest showed increased resonance and fremitus over the right apex posteriorly, with many coarse rales in this area, and a few scattered rales over both bases. The heart was not remarkable. The spleen and liver were not palpable. There was some fullness over the lower abdomen, with an irregular mass in the suprapubic region, extending to the left lower quadrant, where there was local tenderness. The mass was palpable rectally, but there were no nodules within the rectum itself, and sigmoidoscopic examination was negative. On pelvic examination, the entire pelvis felt "frozen," and the uterus seemed connected with the suprapubic mass. The vagina was atrophic, admitting but one finger. The superficial lymph nodes were palpable. The blood pressure was 120 systolic, 80 diastolic.

The temperature was 98.6°F., the pulse 104, and the respirations 24.

Examination of the blood showed a red-cell count of 4,860,000 with 92 per cent hemoglobin, and a white-cell count of 13,750 with 72 per cent mature polymorphonuclears, 6.5 per cent band cells, 2 per cent eosinophils, 0.5 per cent basophils, 8.5 per cent monocytes and 5.5 per cent myelocytes. The serum albumin was 2.8 gm. and the serum globulin 2.6 gm. per 100 cc. The chlorides were 91.8 milliequiv. per liter. The nonprotein nitrogen was 54 mg. per 100 cc. The blood Hinton, Wassermann and Kahn reactions were negative.

The urine showed a ++ test for albumin and a + test for urobilinogen (no urobilin), and the sediment included large round cells, hyaline and granular casts, and 25 to 50 white cells per high-power field.

Stool examination showed positive guaiac and benzidine reactions. Gastric analysis showed 60 units of free acid following histamine. The stomach contents were free of acid-fast bacilli.

A roentgenogram of the chest showed diffuse mottling, most marked at the right base and in the right upper lobe. A flat roentgenogram of the abdomen showed numerous gas-filled loops having the pattern of small intestines. A barium enema passed through the rectum into a slightly elongated sigmoidal loop, the proximal portion of which was definitely narrowed over a distance of 8 cm. adjoining the junction of the sigmoid and descending colon. The contour of the stenosis could not be made out in any detail because of technical difficulties.

While in the other hospital, the patient ran a fever up to 101°F. rectally. Following an unsuccessful attempt to pass a Miller-Abbott tube, she was placed on Wangensteen drainage, and was

given intravenous glucose and salt solution. On the fifth day after admission, she was transferred to this hospital for operation.

Examination at this time was essentially as before. There were no significant changes in laboratory studies except for a rise in the white cell count to 21,100 with 81 per cent polymorphonuclears. Roentgenologic studies were as before, with the additional findings of generalized decalcification of the skeleton, the fracture of a mid dorsal vertebra and small amounts of fluid in both pleural cavities.

The patient was considered too poor a risk for operative intervention. She was continued on the Miller-Abbott tube. On the sixth hospital day, her temperature rose to 101°F, and she rapidly became weaker. Death occurred eight days after admission.

### DIFFERENTIAL DIAGNOSIS

DR ARTHUR W. ALLEN: Are the x-ray films here?

DR JAMES R. LINGLEY: This is evidently the area of narrowing referred to in the sigmoid. The small bowel contains much gas and is moderately dilated, but there is surprisingly little dilatation of the colon above the point of partial obstruction. The chest shows fluid in both pleural cavities and a process in the right upper lobe, the nature of which is not definite from the one film available. It could be an acute pneumonia or a chronic tuberculous infection.

DR ALLEN: The films add nothing to the report. We do see distended loops of small bowel, which means that whatever the cause the patient had intestinal obstruction. If we are to believe this story as it is written, this woman was in comparatively good health until a short time prior to her death. The seven weeks' duration prior to entry and the eight days here in the hospital give her a total illness of less than two months. We are told that during this time she lost 45 pounds in weight, a clear indication that during her present illness she could not have absorbed much nourishment.

The conditions that could produce such a picture as this are numerous. One has to think first of all of some kind of acute inflammatory process as an origin of her difficulty. The possibility of appendicitis has to be considered because that could produce a picture not too different from this with a final mass in the pelvis, with some fixation of the pelvic organs, subsequent obstruction, which might be intermittent, and finally death. Diverticulitis arising from the sigmoid could be another inflammatory cause for such a

picture, but I believe that one would see diverticula in the sigmoid if that had to be seriously considered. The question of Meckel's diverticulum has to be borne in mind, but it is not so commonly met in people of this age as in younger patients. Most of the cases of Meckel's diverticulum that have been operated on in this hospital in adults have had a preoperative diagnosis of intestinal obstruction, with a fairly long history of illness.

Then we come to the other group of diseases that must be seriously considered in a patient of this age, regardless of her well being prior to this present illness—namely, some form of malignant neoplasm. Many facts associated with this particular history and physical examination point toward neoplasm. It is perfectly possible to have had a slowly developing malignant tumor that might quite suddenly produce intestinal obstruction. The fact that the point of intestinal obstruction did not appear actually to be in this narrow sigmoid but somewhere in the small bowel does not mean that the primary disease could not have arisen from this region. The fact that a rectal polyp had been removed two weeks prior to entry makes us seriously consider the possibility of carcinoma of the rectosigmoid, perhaps developing from a polyp, which had worked its way through the bowel wall and produced a mass such as that described. One very significant point is against this possibility: the record states quite clearly that the stools were grossly blood free. They did find a positive benzidine and guaiac test in the laboratory, but carcinoma of the colon arising from a polyp will nearly always produce gross blood. That is a point we have to take into consideration in the differential diagnosis of this particular patient. Another possibility is an ovarian carcinoma that had remained localized for quite a long time and then got out of bounds, producing pressure on the sigmoid or, more likely, a loop of small bowel becoming adherent to the ovarian tumor. The story is quite compatible with such a condition. The spontaneous fracture of the dorsal vertebra is not clear to me, whether it is there or not, I cannot tell.

DR LINGLEY: I do not see it on these films.

DR ALLEN: If present, it would make one think of widespread metastases to the bones, which do rarely occur with cancer of the bowel and a little more often with cancer of the ovary, but are much less common in these two forms of malignant disease than they are with carcinoma of the breast or prostate. The marked decalcification bothers me a little although I think we see that not infrequently in elderly people. There is nothing

## CASE 27452

## PRESENTATION OF CASE

A sixty-year-old man was admitted to the hospital because of lower abdominal pain.

He had always been in fairly good health, except for a chronic "bronchitis," gradually increasing deafness extending over a period of many years and an old "rupture." This hernia had been present for a long time in the right inguinal region and had always been reducible, although occasionally with some difficulty. A truss had been worn, and had given good support.

Three days before entry, the patient noticed slight discomfort in his lower abdomen near the hernia, characterized by a feeling of 'gas.' He paid little attention to his condition at that time, but the next day, when actual pain appeared (localized in the region of the hernia and extending across the lower abdomen), he took a dose of soda bicarbonate and Epsom salts. Following this, his pain increased. Only a scanty bowel movement was produced; the stool contained no blood. During the day, the patient experienced a questionable chill. There was no nausea or vomiting. Late in the third day, he called a physician because his pain had become too great to bear. He was given morphine, and referred to the hospital.

On examination, the patient appeared well controlled by sedation. He was an obese man, with some cough and with wheezing respirations. Loud, coarse rhonchi were heard throughout both lung fields, without other signs. The heart was slightly enlarged toward the left. The abdomen was quite obese. Tenderness and spasm were present in both lower quadrants, especially in the left, where there was some question of a palpable mass. Peristalsis was active. Two hernias were present, one at the umbilicus about 4 cm. in diameter and one extending across the right inguinal region to the scrotum about 12 cm in diameter. Both were reducible. Slight scrotal edema was present. The blood pressure was 120 systolic, 75 diastolic.

The temperature was 102°F, the pulse was 120 and the respirations were 24.

Examination of the blood showed a white cell count of 20,400 with 90 per cent polymorphonuclears, and a red cell count of 4,240,000 with 98 gm hemoglobin. The blood Hinton reaction was negative. The urine showed a ++ test for albumin, with occasional granular casts and white cells in the sediment.

The patient was at once started on sulfapyridine, and a blood level of 3 to 4 mg per 100 cc was maintained. A Miller-Abbott tube was passed. The temperature dropped to 99°F in three days,

and there was definite improvement in his condition. A roentgenogram of the abdomen, taken on the second hospital day, showed a large amount of gas in the stomach and in at least two loops of the small bowel. The tip of the Miller-Abbott tube lay in the pylorus. An ovoid area of increased density, suggesting a stone, was present in the region of the gall bladder.

The extremities became cold and sweaty, and the pulse and temperature rose sharply to 160 and 103°F, respectively. The patient thrashed about in bed, complaining bitterly of lower abdominal pain and voiding incontinently. His abdomen was more distended and firmer than it had been heretofore; peristalsis was absent. The patient was finally brought under sedation. In the next two days there was again considerable improvement in his condition, with a corresponding fall in the temperature and pulse. On the eleventh hospital day, following blood transfusion, the lower abdomen was opened under local anesthesia, by an incision splitting the right rectus muscle. The omentum was found adherent in the pelvis, covering a pocket of pus. Several similar pockets lying between loops of the small intestine were also evacuated. A Witzel enterostomy was made in the left lower quadrant, and the wound closed with drainage. The following day (thirteenth hospital day) respirations became increasingly stertorous and failed.

## DIFFERENTIAL DIAGNOSIS

DR CHAMP LYONS. This patient had a hernia for many years that gave no trouble and was easily reducible. Apparently, it was well controlled by a truss. He entered the hospital after three days of lower abdominal pain, which I interpret as gas pains, although there is no definite statement of their character in the record. Such a lower abdominal crampy pain suggests large bowel obstruction. Two days before entry, the patient took a purgative, which failed to give complete evacuation of the large bowel and increased the pain. I again believe that signifies some degree of large-bowel obstruction. The suggestive chill, the elevation of temperature and the white-cell count consistent with suppurative inflammation all make me think that the large bowel obstruction was associated with some pelvic inflammation. It is significant that there had been no nausea or vomiting such as would be more likely to occur with small bowel than with large bowel obstruction. The pain was so severe as to require morphine; this also suggests a peristaltic type of pain.

May we see the x-ray films? I should particularly like to have Dr Lingley point out the

gas in the large and small bowel and discuss its significance.

DR. JAMES R. LINGLEY: Here is the large area of calcification in the region of the gall bladder. It is quite characteristic of and undoubtedly is a stone. Here is the loop of dilated intestine that is described. It is often very difficult by x-ray study to determine whether such a loop is colon or small bowel, particularly when there is marked dilatation. In this case, I think you can see evidence of the valvulae conniventes of the jejunum rather than the haustral markings of the colon. I should be inclined to think it was small rather than large bowel, even though it is in the region of the transverse colon. No definite masses are visible, although these films were taken with a portable machine and therefore are not of very good quality.

DR. LYONS: The physical examination of the abdomen was of particular interest. There is no note of whether or not the abdomen was distended. The record simply says it was obese. The patient had active peristalsis, again a suggestion of intestinal obstruction rather than a distention of the bowel from ileus or peritonitis. The evidence of inflammation is confined chiefly to the lower abdomen, where there were tenderness and spasm and a questionable mass on the left side. The hernia was still reducible, and evidently there was no incarceration or strangulation. Scrotal edema without edema elsewhere in a man up and about again suggests to me an inflammatory infiltrative process rather than edema on the basis of cardiac failure or low serum protein. The single urine report of a ++ test for albumin, with casts, is inadequate for evaluation of the kidney function. The patient had inflammation and fever on entry, and it might be the albuminuria of the febrile reaction. No blood chemical findings were reported. The failure of the Miller-Abbott tube to pass does not disturb me because it often fails to pass in sick patients. They cannot be taken down to the X-ray Department, where one can manipulate the tube. The gallstone was in the usual position. I rather think we need not consider gallstone ileus because of the lack of symptoms of upper intestinal obstruction. The temperature dropped to 99°F. under bed rest, a consequence presumably of sulfapyridine therapy, which suggests a slow subsidence of the intra-abdominal infection. The acute collapse on the third day of hospitalization is to my mind associated with acute rupture of an abscess or of bowel, with a spread of this inflammatory process in the abdomen. From then on, the symptoms are those of peritonitis. The operative interference appar-

ently did not add much diagnostic information, and enterostomy was done, with decompression of the small bowel.

I shall confine my discussion to those diseases that I think might result in obstruction in the large bowel or arise from inflammation in the region of the large bowel.

Appendicitis with abscess formation one should consider foremost and primarily, but there was too little evidence of associated small-bowel obstruction to make appendicitis a likely possibility. In appendiceal inflammation, obstruction is much more apt to involve small bowel than large bowel. There is too little in the way of a mass to account for the acute illness. Had this been an appendicitis progressing to abscess formation making him as sick as he was, I should think that the patient would have had more of a mass in the abdomen. If this had been acute rupture of an appendix, the symptoms would have been those of peritonitis rather than of large-bowel obstruction.

Carcinoma with secondary perforation must be seriously considered. The lesions of the rectosigmoid are much more apt to give obstruction than to perforate. Perforation of neoplasms of the colon occurs most frequently in lesions above the rectosigmoid.

To my mind, the best diagnosis is diverticulitis. I am a little disturbed about that diagnosis because there was not a sufficient history of previous difficulty. There was no blood in the stool, which might suggest that diverticulitis and carcinoma coexisted. On the other hand, the story of lower abdominal inflammation, with subsequent perforation, does stand out. We must also consider obstruction. Inflammatory diverticulitis may obstruct, but this was rather an acute obstruction for the slowly developing inflammation of a diverticulitis and it is unusual for simple diverticulitis to give generalized peritonitis. Fish-bone or chicken-bone perforation of the diverticulum can produce such a peritonitis, but we have no evidence that that occurred. I believe that this man had diverticulosis for a considerable time, that he then developed large-bowel obstruction distal to the diverticulosis, and that diverticulitis followed as a consequence of this obstruction.

My final diagnoses include umbilical and scrotal hernia, cholelithiasis and diffuse peritonitis, which I believe was the primary cause of death. I think he had diverticulitis with abscess formation and subsequent rupture of the abscess, and I rather suspect there was an obstructing rectosigmoid carcinoma.

DR. ROBERT LINTON: When the record says that the patient was quite obese it is much to the point.

He was so obese that one could not tell whether he was distended or not. He was extremely difficult to handle. When I first saw him, the pain was entirely in the scrotal hernia on the right side. It stayed there for a day and then shifted to the left lower quadrant and subsequently shifted back to the right lower quadrant. The differential diagnosis while the patient was in the hospital lay between appendicitis and diverticulitis, with rupture of either one of them, and as time elapsed the diagnosis seemed to become more obvious. We thought he had diverticulitis, with rupture and abscess formation. The patient was never in any condition to make it possible to perform a laparotomy to relieve him of his trouble. The enterostomy that was made just before death was done chiefly because the Miller-Abbott tube could not be passed, and it was thought that decompression of the small bowel might help him, although little hope of saving him was entertained at that time. The clinical diagnosis, I think, on the record was diverticulitis, with abscess formation and peritonitis.

#### CLINICAL DIAGNOSES

Acute diverticulitis with rupture.  
Acute peritonitis.  
Bronchopneumonia.

#### DR. LYONS'S DIAGNOSES

Diverticulitis, with abscess formation and rupture.

Rectosigmoid carcinoma?  
General peritonitis.  
Umbilical and inguinal hernias.  
Cholelithiasis.

#### ANATOMICAL DIAGNOSES

Carcinoma of sigmoid.  
Perforation of sigmoid.  
General peritonitis, acute.  
Diverticulosis of colon.  
Polyps of sigmoid.  
Umbilical hernia.  
Inguinal hernia, right.  
Operative wound; ileostomy.

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This patient had diverticulosis of the colon, polyps and carcinoma. The carcinoma was an annular affair, which produced very severe obstruction. We found a perforation of the bowel 13 or 14 cm. back from the cancer. It appeared to be a spontaneous rupture of the intestine, possibly at the site of a diverticulum, although we could not determine that with any certainty. There was no local inflammatory process, although, of course, there was a generalized peritonitis. We could not make out evidence of successive stages of peritoneal inflammation. There was a very large gallstone, but nothing else of clinical significance.

peritoneal involvement and, probably, rupture, and indicate laparotomy. There is no evidence in the record that a vaginal examination was made. If it had been, tenderness, if not a distinct mass, would undoubtedly have been recognized in one vault or the other, and early laparotomy would have prevented this obstetric disaster. No matter how lenient one may be in attempting to place responsibility for this particular fatality, mistaken diagnosis seems to be the only cause of death.

## DEATHS

**JOHNSON**—ELMON R. JOHNSON, M.D., of Quincy, died October 30. He was in his seventy-first year.

Born in Hancock, Dr. Johnson received his degree from Boston University School of Medicine in 1895. He had been a member of the staff of the Quincy City Hospital. He was a fellow of the American College of Surgeons, the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, three daughters, two sons and two brothers.

**LEONARD**—JOHN M. LEONARD, M.D., of Fall River, died October 26. He was in his sixty-sixth year.

A native of Fall River, Dr. Leonard received his degree from the College of Physicians and Surgeons of Baltimore in 1900. He was a fellow of the Massachusetts Medical Society and the American Medical Association. He had been president of the staff of St. Anne's Hospital, Worcester, since 1937, and medical inspector of public schools for thirty-three years.

His widow, a daughter and three sons survive him.

**MACDONALD**—FREDERICK C. MACDONALD, M.D., of Boston, died October 27. He was in his sixty-sixth year.

Dr. MacDonald received his degree from Tufts College Medical School in 1901. He was a member of the Massachusetts Medical Society and the American Medical Association.

**VICKERY**—LUCIA F. VICKERY, M.D., of Jamaica Plain, died October 23. She was in her eighty-second year.

Born in Portland, Maine, Dr. Vickery received her degree from the Woman's Medical College of the New York Infirmary for Women and Children in 1892. She was a member of the Massachusetts Medical Society and the American Medical Association.

## CORRESPONDENCE

### POSTOPERATIVE RADIUM THERAPY

*To the Editor:* In the article, "Carcinoma of the Endometrium," by Dr. G. V. Smith, appearing in the October 16 issue of the *Journal*, the author concludes, "Preoperative and postoperative application of radium and x-radiation are considered valuable and probably necessary adjuncts to the best management of endometrial cancer."

Experience with the vaginal application of a 100-mg. bomb of radium to the cervical area, following total or supra-vaginal hysterectomy, was cited. An effective dosage of at least 2400 mg. hr., and at most 6000 mg. hr. in two applications within eight weeks of each other, was given.

The purpose of this letter is to inject a strong word of caution in the use of radium against the cervical stump or the site of the removed cervix, following total hysterectomy. It must be remembered that since the uterus has been removed, the pelvic viscera, namely, the small and large intestines, lie very close to the cervical stump or the area of the removed cervix. Hence, the intestine itself may be exposed to a large portion of the radium dosage given. This may result in various degrees of radionecrosis, manifested by diarrhea and cramps and later by intestinal obstruction due to adhesions or by perforation, peritonitis or the early development of an intestinovaginal fistula.

There is no effective way of screening the intestines when applying radium after hysterectomy, whether this be total or subtotal. This possible hazard should be kept constantly in mind. It looms large as a pitfall only in the hands of the occasional user of radium.

HOLLIS L. ALBRIGHT, M.D.

412 Beacon Street  
Boston

\* \* \*

The above letter was referred to Dr. Smith, whose reply was as follows:

*To the Editor:* Dr. Albright misquotes the last paragraph of my "Summary and Conclusions," which begins "Preoperative or postoperative," not "Preoperative and postoperative." Five times in the paper I refer to the use of radium before or after operation. We do not apply radium before and after operation, except in rare cases.

Concerning the cases covered in the review, namely, through 1935, the postoperative dosage of radium and screening are accurately described in the paragraph on "Postoperative radiation." The largest postoperative dose was 3000 mg. hr. In the following paragraph, I should have stated that our postoperative doses since 1935, although at least 2400 mg. hr., have never exceeded 3000 mg. hr. With the screening described, namely, 1.0 mm. of brass and 2.0 mm. of lead in addition to the 0.5-mm. silver capsule containing the radium, this dose has been found safe, as attested by the absence of complications in those so treated and carefully followed since 1935. Concerning this same paragraph, Dr. Albright makes a misstatement to the effect that a dosage of at most 6000 mg. hr. was given following hysterectomy. Actually the sentence reads, ". . . at least 2400 mg. hr. postoperatively, and two applications two to eight weeks apart, totaling 4800 to 6000 mg. hr., for those not operated on." Only patients *not* operated on receive the large doses, and these, too, are heavily screened.

At the Free Hospital for Women, where we treat approximately 150 new cases of cancer yearly and follow 300 to 400 treated cases during each year, all the possible hazards of irradiation are of necessity constantly in our minds in connection with the type and extent of the disease, the condition of the patient and operative procedures. To those of us who are using radium on an average of two to three times a week, the possible hazards loom large as pitfalls, which we must be on the alert to avoid if we can and which we often are forced to accept in situations where the likely advantages appear to outweigh the con-

ceivable disadvantages. Although we use radium often and despite our best judgment, unpredictable and unavoidable complications do develop. Therefore I take exception to Dr Albright's statement that the possible hazard of applying radium after hysterectomy looms large as a pitfall only in the hands of the occasional user, although we happen to have been fortunate in the results of our postoperative applications.

I heartily endorse his words of caution but point out that the lethal and disabling complications of carefully planned radiation are relatively rare and that considerable risk is warranted when one is aiming to render patients free of cancer.

GEORGE V SMITH, MD

Free Hospital for Women  
Brookline, Massachusetts

### ACCIDENTAL MALARIAL INFECTION

To the Editor: In a recent paper in *Venerical Disease Information* (22:271-276, 1941), concerning the technique of induced malaria used in the South Carolina State Hospital, the special point is made that patients undergoing malarial therapy should be kept isolated in a screened ward. The authors remark that some of the malarial strains examined by them and supposed to be free of gametocytes were, in fact, no different from other strains and were potentially dangerous because of the presence of these gametocytes and hence the possibility of transfer from patient to patient by certain species of mosquitoes. They also refer to reports from Europe of outbreaks of malaria because anopheline mosquitoes easily came in contact with patients undergoing malarial therapy.

It might be thought that especial attention need be given these points in the northern part of the United States, but this is apparently not so. A superficial study of an accidentally contracted unexplained case of malaria in a Boston hospital in 1940 brought out some interesting facts. The subject was a house officer whose duties included malarial treatment. While in the hospital during the winter of 1940 he was bitten several times by mosquitoes which were not identified. Within a reasonable incubation period (four to five weeks) from the date he was bitten he came down with tertian malaria. During that period he had injected malarial blood into several patients without known untoward accident. The last injection was given by him eleven days before he himself became ill. Fourteen days before he became ill he gave a 500-cc transfusion to a patient who had never had malaria and who had never been outside Massachusetts. This patient did not develop malaria. Malariaologists pointed out that the failure of the recipient to contract malaria probably but not certainly excluded the existence of malarial infection in the house officer at the time of the transfusion. Since the house officer was a reasonably careful worker, had no skin abrasions and recalled nothing unusual about the injections of malarial blood he had given to ward patients, the way in which he contracted malaria is not evident.

Stained slides of the blood of patients on his ward inoculated with tertian malaria were examined by parasitologists at the Harvard Medical School. Despite the fact that the strain of malaria used at this hospital had been circulated from patient to patient for some fifteen years gametocytes were easily found on these slides. A careful search for mosquito breeding places was planned but was

quite unnecessary. Within five minutes from the start of the search, a possible breeding place, a large shallow pool (10 by 20 feet) of water about some boilers, was found. Many adult mosquitoes were flying around in March and the men working in the boiler room said the mosquitoes had bitten them all through the winter. Several hundred larvae from this pool and a smaller number of adult mosquitoes were examined, but all were found to belong to the *Culex* genus, which, of course, has never been incriminated as a carrier of malaria. A recent survey in Suffolk County revealed that anopheline mosquitoes are occasionally present there in the summertime, and it is possible that a breeding place harboring this genus might have been found if a more thorough search had been made.

In any event it is apparent that, with the presence of gametocytes in the blood of patients undergoing malarial therapy, extreme care should be taken to avoid accidental infection.

### BOOK REVIEW

*In Search of Complications: An autobiography*. By Eugene de Savitsch, MD. Foreword by Arthur Krock. 8°, cloth. 396 pp. New York: Simon and Schuster, 1940. \$3.00.

This is another in the seemingly endless list of medical autobiographies and memoirs that the last few years have produced. Dr de Savitsch is a Russian whose life has been spent in his own country and Japan and the United States where he studied medicine and where he practices. He has had some lively adventures, which he narrates with a certain verve, but the most interesting antedate his entry into medicine. Of the current Russia which in the present status of world events one craves to know, nothing is said in this work. Dr de Savitsch is a White Russian, and he has been away too long. The reviewer confesses to no more than a mild interest in this book. A jaded appetite for this type of literature (unless something, really outstanding came along) may be responsible.

### NOTICES

#### SOUTH END MEDICAL CLUB

A regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 254 Columbus Avenue, Boston, on Tuesday, November 18, at 12 noon.

Dr H. Houston Merritt will speak on "Treatment of Epilepsy."

#### JOSEPH H. PRATT DIAGNOSTIC HOSPITAL

Bennet Street Boston  
Lecture Hall, 9-10 a.m.

#### MEDICAL CONFERENCE PROGRAM, NOVEMBER

Wednesday, November 12—The Dynamics of Niral Respiration. Dr H. J. Sternstein.  
Friday, November 14—Some of the Disputed Points in the Treatment of Syphilis. Dr W. P. Boardman.

Saturday, November 15—Presentation and discussion of District and Boston Floating Hospital cases. Dr. P. Piccolo and Dr. Francis McDonald.

Wednesday, November 19—Refractory Blood Diseases. Dr. C. W. Heath.

Friday, November 21—Anemia and Hiatus Hernia. Dr. William P. Murphy.

Saturday, November 22—Blood Clinic. Dr. H. G. Brugsch.

Wednesday, November 26—What Happens to Alcoholics? Dr. Merrill Moore.

Friday, November 28—Gold Therapy of Rheumatoid Arthritis. Dr. Charles L. Short.

Saturday, November 29—Personal Experiences with Wartime Neuroses. Dr. Kurt Goldstein.

On Tuesday and Thursday mornings (except November 11 and November 20) from nine to ten o'clock, Dr. S. J. Thannhauser will give a medical clinic on hospital cases

### PETER BENT BRIGHAM HOSPITAL

Gordon Gordon-Taylor, O.B.E., M.A. (Abert.), M.S., B.Sc. (Lond.), F.R.C.S., F.R.A.C.S. (hon.), senior surgeon to the Middlesex Hospital, London, and surgeon rear-admiral to the Royal Navy, will be surgeon-in-chief *pro tempore*, at the Peter Bent Brigham Hospital, Boston, from November 9 through November 15. All physicians are cordially invited to attend the regular hospital exercises in which he will participate, that is, the clinicopathological conference on Monday, November 10, at 12:15 p.m., the surgicopathological conference on Wednesday, November 12, at 4:00 p.m., and the joint Peter Bent Brigham Hospital—Children's Hospital rounds (at the Children's Hospital) on Thursday, November 13, at 8:30 a.m.

### HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held in the amphitheater of the Peter Bent Brigham Hospital on Wednesday, November 12, at 8:15 p.m.

#### PROGRAM

Clinical presentation.

Remarks Concerning Military and Naval Surgery. Mr. Gordon Gordon-Taylor, O.B.E., surgeon to Middlesex Hospital, London; surgeon rear-admiral to His Majesty's Navy; surgeon-in-chief *pro tempore*, Peter Bent Brigham Hospital.

Physicians and medical students are cordially invited to attend.

### BOSTON DOCTORS' SYMPHONY ORCHESTRA

The Boston Doctors' Symphony Orchestra will rehearse, under Alexander Thiede, every Thursday at 8:30 p.m. at Station WMEX, 70 Brookline Avenue, Boston. Those interested in becoming members should communicate with Dr. Julius Loman, 520 Beacon Street, Boston (KEN 3200 or L 2N 2155).

### MASSACHUSETTS DEPARTMENT OF CIVIL SERVICE AND REGISTRATION

Medical Inspector (Part-Time), Health Department, \$2000 a year, Boston

Director of State Civil Service, Ulysses J. Lupien, has announced that a competitive examination is to be held on December 13, to find eligibles for appointment to the position of part-time medical inspector, Health Department, Boston.

The entrance requirement is as follows: applicants must be registered physicians under the Massachusetts Board of Registration in Medicine. The subject and weights of the examination are as follows: training and experience, 2; practical questions, 3; total, 5. To become eligible, applicants must obtain a grade of at least 70 per cent in each subject. The last date for filing applications is Saturday, November 22, at 12 noon.

### NATIONAL COMMITTEE FOR MENTAL HYGIENE FELLOWSHIPS

A limited number of fellowships are being offered for training in extramural and child psychiatry. Initial selection for these fellowships is to be made by the National Committee for Mental Hygiene, and eligible applicants will be recommended for appointment in selected training clinics. These fellows will spend one or two years in a clinic, the term and plan of the fellowship to be determined by the peculiar needs of the applicant. The training is pursued according to a definite plan related to the probable future functions of these fellows. Candidates for fellowship award should have had at least a general internship and two years of psychiatry in an approved mental-hospital service, in addition to other qualities fitting them for extramural service. Since this provision of training fellowships comes in response to a definite paucity of personnel in this field, peculiarities of the demand are considered in making appointments. The stipends vary slightly with location and status of the fellow but in general range between \$2000 and \$2600.

Requests for further information about these fellowships, and applications therefor, should be addressed to Dr. Milton E. Kirkpatrick, National Committee for Mental Hygiene, 1790 Broadway, New York City.

### SOCIETY MEETINGS AND CONFERENCES

#### CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, NOVEMBER 9

##### MONDAY, NOVEMBER 10

12 15-1 15 p.m. Clinicopathological conference Peter Bent Brigham Hospital amphitheater

##### TUESDAY, NOVEMBER 11

12 15-1 15 p.m. Clinicorontgenological conference. Peter Bent Brigham Hospital amphitheater.

##### WEDNESDAY, NOVEMBER 12

## A STUDY OF INFLUENZA IN BOSTON DURING THE WINTER OF 1940-1941<sup>1</sup>

HAROLD E. PEARSON, M.D.,<sup>1</sup> EUGENE C. LEECHER, M.D.,<sup>2</sup> JOHN H. DINGLE, M.D.,<sup>3</sup>  
AND JOHN F. ENDERS, PH.D.<sup>4</sup>

BOSTON

**A**N epidemic of influenza during the fall and winter months of 1940 and 1941 affected almost every section of the United States. A sharp rise in the incidence of this disease was recorded in California during November, and a peak of about 37,000 cases was reported from the Pacific and Mountain regions for the week ending December 21. The regions of the Southeast presented a maximum of about 58,000 cases during the week of January 11, and the South Atlantic region one of about 50,000 cases in the week of January 25. According to the statement in *Public Health Reports*,<sup>1</sup> "In the East North Central, West North Central and New England regions the disease did not appear until about the middle of January and in the Middle Atlantic region the highest weekly incidence was reported during the week ended February 1st."

The total influenza morbidity reports as given by *Public Health Reports* for New England for the period from December, 1940, through March, 1941, are assembled in Table 1. These data suggest that the outbreak in New England became evident suddenly, rapidly attained a maximum about the middle of January, and subsided abruptly.

It will be noted that no figures for Massachusetts are included in the table, since in this state the disease is not reportable. Recorded deaths, however, from influenza in Boston were 4 in December, 22 in January, 11 in February

and 4 in March. The following statement, moreover, has been published: "It was reported January 11 that 18,000 school children in Boston were ill with a mild form of the disease. Classes had been suspended in Salem, Haverhill and Gardner, Massachusetts."<sup>2</sup> During January, the average

March 29	1	0	0	8	2	11

daily attendance of 134,000 grammar school and high school children in Boston decreased 8 per cent, as compared with the records for December and February.<sup>3</sup> Reportable communicable diseases were not unusually prevalent during this period.

During the outbreak in Boston, clinical and laboratory studies of respiratory illnesses occurring in two groups of adults, some of whom had been vaccinated against influenza, were carried out. In addition, serums from certain pneumonia patients entering a large city hospital throughout this period were examined serologically. The findings are described in this communication.

### METHODS

The two groups selected for study consisted of 404 students at the Harvard Medical School and 558 members of the personnel of the Boston City

<sup>1</sup>From the Department of Bacteriology and Immunology, Harvard Medical School and School of Public Health, the Department of Hygiene, Harvard University, the Thayer Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School.

<sup>2</sup>Formerly student, Harvard School of Public Health.  
<sup>3</sup>Instructor in medicine, assistant in preventive medicine and assistant medical adviser, Harvard Medical School.

<sup>4</sup>Instructor and Francis Well Peabody Fellow in Medicine and Instructor in Bacteriology, Harvard Medical School; assistant physician, Thayer Memorial Laboratory, Boston City Hospital.

<sup>5</sup>Assistant professor of Bacteriology, Department of Bacteriology, Harvard Medical School.

Hospital. Approximately half the former group received, on January 6, the "complex chick-embryo vaccine" (canine-distemper virus and influenza A virus).<sup>4</sup> About two fifths of the latter group were given this vaccine on January 8. Serums were taken immediately before the administration of vaccine, and four weeks later from the vaccinated and nonvaccinated medical students. Serums were

37°C. for one hour, 0.5 cc. of 2.5 per cent sheep cells sensitized with 2 units of amboceptor was added and incubation continued for forty-five minutes. Final readings were taken after overnight storage in the refrigerator. The test was considered significant when the titer of the second serum specimen was four or more times greater than that of the first serum taken. Complement-

FIGURE 1. *Distribution of Cases of Clinical Influenza and Other Illness in Hospital and Student Groups according to Time of Onset.*

taken from the hospital group at the time of vaccination and again three weeks later. Complement-fixation tests with influenza A virus as antigen were carried out on all these serums, and, as previously mentioned, on certain serums from cases of pneumonia in the Boston City Hospital. The technic employed was similar to that of Eaton and Rickard.<sup>5</sup> To 0.25 cc. of serum was added 2 units of complement, saline to a total volume of 0.75 cc. and 0.25 cc. of antigen (a 2 per cent suspension of mouse lung infected with influenza A virus [Strain PR 8]\*). After incubation at

fixation tests<sup>6</sup> on some of the same serums, using influenza B virus (Lee strain),\* were carried out by the same procedure, except that a 5 per cent suspension of infected mouse lung was used as antigen. Serums known to be positive were included as controls in all tests, as well as normal mouse lung (2 or 5 per cent suspension) and the usual serologic controls.\*

The titer of a serum was recorded in terms of its final dilution in the volume of fluid present before the addition of the sensitized cells. The end point was taken as the dilution of serum that gave complete fixation in a final dilution of 1:16 and slight fixation in higher dilutions. Certain

\*We are indebted to Dr. Frank L. Horsfall, Jr., Rockefeller Foundation, New York City, for the influenza A virus and positive serums, and to Dr. Thomas Francis, Jr., New York University College of Medicine, New York City, for the influenza B virus.

investigators have expressed the titer in terms of the original dilution of the serum. Although we should like to adhere to this practice for the sake of conformity, it is evident that this makes it impossible to compare satisfactorily the results of different investigators unless comparable concentrations of reagents are universally employed.

Influenza A virus was isolated by the intranasal inoculation of ferrets with throat washings obtained from patients. With material from infected ferrets, mouse passages were initiated.

Virus neutralization tests in mice were done with serums of 2 cases from which virus was recovered; 0.05 cc. of a mixture of equal parts of infected mouse lung (1:1000) and dilutions of serum was inoculated intranasally. The neutralization titer of the serum was expressed in terms of its final dilution.

Cross-neutralization tests in mice were carried out with immune rabbit serums prepared by the single intraperitoneal inoculation of 10 to 12 cc. of a 10 per cent suspension of the lungs of mice infected with the several strains of virus examined. The rabbits were bled ten to seventy-two days following injection.

The persons studied were classified under three headings, according to the clinical history. Under "clinical influenza" were included all those who gave a history of illness characterized by sudden onset, fever above 99°F. and constitutional symptoms such as weakness, and muscle, bone or joint pains. Under "other illness" were assigned those who had any illness of the respiratory tract other than clinical influenza, as characterized by all the foregoing criteria, or of an ill-defined nature. Under "no illness" were listed those who had no illness during the period of observation.

In both the student and hospital groups, serologic data secured for the month of January are presented. The students returned to school on January 3, after the Christmas recess. A few had been ill either in Boston or elsewhere during the recess, and were accordingly excluded from the serologic study.

## RESULTS

Figure 1 presents by weeks the number of cases of clinical influenza and other illness in the hospital and student groups for the period of three months, according to the time of onset. The distribution of cases according to the clinical classification is similar. In the hospital group, 90 per cent of the cases of clinical influenza and 80 per cent of the cases of other illness occurred from December 17 to February 1. For the student group,

the figures are 79 and 66 per cent, respectively. The peak of maximum illness in both classes occurred about the middle of January. There is thus a suggestive chronologic parallelism between the incidence of influenza and other respiratory illness.

The incidence of illness during January is presented in Table 2. It is evident that about half the patients in each group were ill, and that in about one sixth of both groups these illnesses were diagnosed as influenza.

The results of complement-fixation tests for influenza A virus with serums from the student and

TABLE 2. Incidence of Illness in Medical Students and Hospital Personnel during January, 1941.

ILLNESS	MEDICAL STUDENTS		HOSPITAL PERSONNEL	
	NO. OF CASES	PER CENT	NO. OF CASES	PER CENT
Clinical influenza	58	14	108	19
Other illness	125	31	137	25
No illness	221	55	313	56
Totals	404		558	

hospital groups are given in Table 3. On the assumption that a fourfold rise or more in titer of complement-fixing antibodies indicates recent influenza infection,<sup>2</sup> 18 per cent of the nonvaccinated group had had recent contact with this

strain of virus. Thirty-five (22 per cent) of the 158 in this group showed titers of 1:64 or higher. Seven nonvaccinated and 4 vaccinated persons having clinical influenza experienced no rise in titer. Three of the former had initial titers of 1:64.

In none of these 11 cases was a rise in complement-fixation titer for influenza B virus demonstrated, yet clinically the illnesses could not be distinguished from those in cases that revealed

a significant rise in titer for influenza A virus. Moreover, all the serums from the 44 persons in the vaccinated group at the hospital, together with those from 82 pneumonia patients in the same institution, were tested for complement fixation with influenza B virus. None exhibited a rise in titer, although 4 had titers (1:64) above 1:16. These findings suggest that influenza B virus in all probability played no etiologic role in the groups studied.

About one fifth (10) of the 46 nonvaccinated persons having other illnesses showed significant rises in titer. All but 3 of these, however, had symptoms of clinical influenza, but no temperatures were recorded. It is noteworthy that about 8 per cent (7) of the 92 nonvaccinated persons with no history of illness also had serologic evidence of a reaction to influenza A virus.<sup>5</sup>

Vaccination alone seems to increase complement-fixation titers in certain persons, as shown by comparisons between the vaccinated and nonvaccinated groups as a whole and between the various clinical classifications (Table 3). For example, 47 per cent of the vaccinated group of medical students exhibited a fourfold rise or more in titer compared with 18 per cent in the control group. In the vaccinated group of students who had no illness, 16 per cent showed rises, whereas in only 4 per cent of the corresponding class in the nonvaccinated group did similar changes occur. The high incidence of increases in titer found for the class with no illness at the hospital, as contrasted with that for the corresponding class in the medical-student group, may possibly be accounted for by the probable greater chance of exposure in the institution, which would tend to a larger number of inapparent infections.

#### CLINICAL ASPECTS

A review of 50 case histories of the students with clinical influenza revealed that all but 2 had a sudden onset, and a fever (100 to 102°F.) lasting three days was common. A few had temperatures as high as 104°F. The duration of fever did not exceed four days. Headache, muscle or joint pains and sore throat were characteristic complaints. The acute symptoms usually subsided with the fever, or one to two days later. The majority developed coryza and a cough that usually was not productive and persisted one to two weeks. Weakness was a major complaint and lasted more than one week in about half the cases. Thirteen students were hospitalized. Complications occurred in only 1 patient, who developed otitis media and recovered.

The duration of illness, as indicated by absence

from duty in 117 cases of clinical influenza in the hospital group, is shown in Table 4. In 40 per cent, disability lasted over one week, and in 9 per cent over two weeks.

Of 358 persons in the hospital group with clinical influenza (150 cases) or other illnesses (208

cases) during December through February, 7 cases of pneumonia and no deaths occurred. Three of these complicated influenza, of which one was severe. One other patient had a Type 8 pneumococcus in the sputum. Bacteriologic examination of the sputums of the other patients did not reveal any organisms responsible for the pneumonia. Unfortunately, no serums from these patients were available for study.

Serums from a number of patients with pneumococcal pneumonia admitted to the Boston City Hospital from December through April were available for study. These serums had been collected at random, primarily for studies in pneumococcal immunity by Dr. Maxwell Finland and his associates. From each patient, however, a typable pneumococcus was obtained by culture of the sputum, throat swab or blood. In addition to the various types of pneumococci (Types 1, 2, 3, 4, 5, 7, 8, 14, 18 and 19), cultures of the sputum or throat yielded in some cases alpha-hemolytic streptococci, *Haemophilus catarrhalis*, *H. influenzae*, staphylococci or diphtheroids—the usual flora of the respiratory tract.

During the same period, an unusually large number of cases of staphylococcal pneumonia occurred, often associated with clinical influenza or occurring as a complication thereof. Cultures of the sputum or blood from these patients yielded hemolytic *Staphylococcus aureus* as the predominant organism, although in a few patients alpha-hemolytic or beta-hemolytic streptococci or *H. influenzae* was also present in the respiratory tract. Details of the clinical features of these patients have been reported by Finland, Strauss and Peterson.<sup>7</sup>

Serums from a few of the cases of staphylococcal

pneumonia, together with all those from the cases of pneumococcal pneumonia, were tested for complement fixation with influenza A virus. In certain cases, there was only a single specimen, and in others several specimens obtained over a period of more than a month were examined.

The results are given in Tables 5 and 6. The high incidence of complement-fixation titers of

influenza A virus. The first specimen of these pairs of serums was obtained less than ten days, and the second more than fourteen days, after the onset of illness. One of these cases occurred in April, well after the influenza outbreak had subsided. Of the 9 patients with staphylococcal pneumonia, 3 showed rises and 3 showed decreases in titer that were considered significant.

1:16, died, and the presence of influenza A virus was presumptively demonstrated in the lungs.\*

Eight of 24 serums from the pneumonia cases for which two samples were available showed a significant rise in complement-fixation titer for

\*A ferret inoculated intranasally with a suspension of the lung of this patient developed no signs of infection, but proved refractory to subsequent inoculations with influenza A virus (Strain PR 8). The ferret's serum taken prior to the second inoculation protected mice against infection with this strain of virus.

As previously stated, complement-fixation tests with influenza B virus were done on all serums from the pneumonia patients. No rises in titer and no high titers—3 had titers of 1:64—were found. Furthermore, no correlation could be established between the type of throat flora and the presence of either a high antibody titer or an increase in titer for influenza A virus in the blood of these patients.

#### STUDIES WITH VIRUSES ISOLATED FROM THROAT WASHINGS

Two strains of influenza virus were isolated from the throat washings of 2 patients seen on January 3 and January 11, respectively. Ferrets that were inoculated intranasally responded in the first passage with fever and signs of nasal involvement. Ferrets were inoculated in series at intervals of two to five days, turbinates or a mixture of turbinates and lung tissue being used for transfer. All exhibited signs of infection. If only a small quantity of virus was present, however, in the throat washing (for example, after passage through a Berkefeld filter), no sign of infection in the first passage was seen, but when the ferret was allowed to recover, its serum contained neutralizing antibodies, as demonstrated by the mouse-protection test.

The convalescent serums of ferrets recovered from infection with either strain of virus had

high titers of neutralizing antibodies when tested against influenza A virus (Strain PR 8) in mice. In addition, both persons from whom virus was obtained had a significant rise (1:4 to 1:64 and 1:16 to 1:64, respectively) in titer of neutralizing antibodies, as well as a rise in complement-fixation titers when tested with this strain of virus.

Passage of virus from ferrets to mice did not succeed until the fifth and sixth ferret passages. Mice did not die until three mouse passages had been carried out. The virulence of the virus in infected mouse lungs gradually increased. Thus, 0.05 cc. of infected mouse lung of the twelfth passage, diluted 1:1000, was lethal for mice, whereas the same volume of lung suspension from the twentieth passage killed in a dilution of 1:100,000.

The antigenic relations of the two strains of recovered virus and of the influenza A virus (Strain PR 8) were investigated by means of cross-neutralization reactions, with immune rabbit serums prepared against each strain. The results of these tests are not presented in detail. They indicated, however, that antigenic differences existed among the three strains.

#### DISCUSSION

The epidemiologic, clinical and laboratory findings presented in this paper show that an outbreak of acute upper respiratory disease, studied in Boston during the winter of 1940-1941, was in part due to epidemic influenza. In the majority of cases diagnosed as influenza, influenza A virus appeared to be the etiologic agent. This is based on the following facts: viruses of this type were isolated from the throat washings of 2 typical cases; many patients exhibited rises in complement-fixation antibodies for the influenza A virus following their illnesses; and in a fairly large number of serums, no complement-fixing antibodies could be demonstrated for influenza B virus.

In accordance with the epidemiologic pattern noted in previous outbreaks, the characteristic rapid rise and fall in incidence was observed. Relatively few cases were noted during the last two weeks in December. Increasing sharply to a maximum in the second week of January, the number of cases had by the end of that month again reached a low level of incidence. It is of interest in respect to the problem of the interepidemic persistence of this disease that scattered cases occurred as late as April 1. During the month of January, about half the persons under observation had either influenza or some other illness. Many of these infections, however, were apparently not due to known strains of the influenza virus. This parallelism between influ-

enza and other illnesses may, of course, be attributable to chance, but since similar phenomena have been described by others, it is possible that the same factors responsible for the spread of influenza were operative in that of the undefined infections.

From a clinical standpoint, the uncomplicated disease was in general mild, but otherwise typical of influenza as described in other recent outbreaks.<sup>8-10</sup> In the combined hospital and student groups, only 7 cases of pneumonia occurred during the observation period of three months. Of these, only 3 appeared to complicate clinical influenza.

Examination of serums from 82 patients with pneumococcal and 9 patients with staphylococcal pneumonia revealed that an unusually large number had titers high enough to suggest recent exposure to the influenza A virus. In 27 of these patients, samples of serums were available and were adequate for testing whether or not a close association between the virus and the bacteria was present at about the same time. In 5 of 21 cases of pneumococcal pneumonia, the serologic evidence indicated an associated infection with influenza A virus, and such evidence was obtained in all 6 patients with staphylococcal pneumonia. Although a causal relation between the influenza and the pneumonia has thus not been demonstrated by either clinical or laboratory evidence, it seems possible that in certain of these patients, at least, influenza represented a factor predisposing to the pneumonia.

One of the important objectives, of course, in studies of this kind is to accumulate information that may lead ultimately to means of more certain recognition of the disease. It is therefore pertinent to compare the results obtained in this investigation by means of complement-fixation tests with the clinical diagnosis.

The cases studied during the epidemic period were classified clinically as clinical influenza and other illness. In the unvaccinated student group, it was found that 7 among 20 of those comprising the former class exhibited no increase in complement-fixation titer, whereas 10 among 46 of the latter class showed a significant rise. These findings, then, do not seem to indicate a close correlation between the two methods of diagnosis.

This discrepancy may be attributed to several factors. One of these is the inadequacy of certain of the clinical records. For example, 7 of the patients with other illness who showed rises in titer had all the clinical manifestations regarded as diagnostic of influenza, but their temperatures were not recorded. Had the records been avail-

able, these patients would without much doubt have been included in the influenza group, and thus the percentage of correlation would have been raised from 65 to 74. Then only 3 who showed an increase in titer would have been left in the group of 39 patients with other illnesses, giving a correlation of about 92 per cent between the serologic and clinical diagnoses.

Imperfect recording, however, cannot offer an explanation for the fact that 7 patients in the clinical influenza class apparently underwent a disease typical in all respects of influenza, yet showed no evidence of antibody increase for either influenza A or B virus. This behavior may be accounted for by failure of these persons to produce antibodies detectable by the methods employed, or it may be the result of infection with one or more serologically distinct types of virus, as yet unidentified.

However this may be, at the moment the correlation between the serologic diagnostic test and clinical diagnosis, not only in this study but also in that carried out recently by Dalldorf and his associates,<sup>10</sup> is not so close as one might wish.

The fact that in the nonvaccinated student groups 8 per cent of those having no illness gave serologic evidence of recent contact with influenza A virus is in accord with the figure of 6 per cent in analogous groups recorded by Eaton and Rickard.<sup>5</sup> The epidemiologic role of this sort of patient requires investigation, since he might represent an important factor in the transmission of the virus were his function as a carrier demonstrated.

It should be noted that in this discussion we have confined ourselves to the data obtained in the nonvaccinated group. This was necessary because our findings suggest that vaccination might lead to a fourfold or greater increase in titer of complement-fixing antibodies, thus rendering doubtful the significance of the data obtained in the vaccinated group in respect to the association between rises in titer and clinical diagnosis.

The increase in complement-fixing antibody in certain persons following vaccination is in contrast to the findings of Morrison and his co-workers<sup>11</sup> that repeated vaccination with active chick-embryo virus (influenza A virus [Strain PR 8]) did not induce the formation of this antibody, although neutralizing substances made their appearance.

Our experience with vaccination once again illustrates the futility of attempting to induce active immunity in the face of an outbreak of a disease characterized in its epidemic pattern by sudden appearance and rapid defervescence. Since antibodies do not normally appear before about the

seventh day following the onset of illness, vaccination probably would not lead to an effective state of resistance before this time. Indeed, even a longer interval is perhaps required. All but 8 cases of influenza occurred among the vaccinated persons during the two weeks following vaccination. The data therefore do not present a basis for an adequate estimate of the value of the mode of vaccination employed, but it is noteworthy that clinical influenza may occur in persons who have been vaccinated two weeks before the beginning of their disease. In evaluating this fact, however, one must remember that, because of the rise of antibody induced by the vaccine, we could not determine by serologic test whether the etiologic agent in these cases was influenza A virus. Nevertheless, because of the high incidence of nonvaccinated cases due to this agent, the probability is that certain of these patients were infected with influenza A virus.

Dalldorf and his associates<sup>10</sup> have recently analyzed the incidence of influenza A among persons who had received the complex vaccine of Horsfall and Lennette several weeks before their illness. Protection was not evident as a result of vaccination, but the authors believed that complications were prevented.

Although there can be no doubt that the two strains of virus isolated from patients during the epidemic belonged to the group of viruses now designated influenza A, they exhibited differences indicating that they were not identical. Cross-neutralization tests with antisera prepared in rabbits against these and Strain PR 8 suggested definite though minor antigenic differences. Magill and Francis<sup>12</sup> have described analogous dissimilarities in antigenic composition in various strains of influenza A, and even in those derived from cases in the same epidemic. Our observations, then, add to the evidence for the marked heterogeneity of strains of influenza A, which possibly depends either on the existence of very large numbers of different strains with fixed antigenic properties or on an extreme tendency to variation on the part of a single virus.

#### SUMMARY

An epidemic of influenza occurred in Boston during December, January and February, 1940-1941, which appeared to be a part of an outbreak extending throughout most of the United States.

In Boston, three groups were studied: medical students, hospital personnel and patients hospitalized for pneumonia.

The uncomplicated disease was mild. Complications were rare among the medical students and

hospital personnel, but in a series of 91 pneumonia patients, serologic evidence indicating that a large number had had contact with influenza A virus suggested a possible relation between the two diseases.

Influenza A virus was isolated from 2 patients and was shown by serologic tests to be the chief etiologic agent in the outbreak.

No evidence for infection with influenza B virus was obtained, although certain patients with typical manifestations of clinical influenza gave no indication of a recent infection with influenza A virus.

The correlation between the clinical and serologic means of diagnosis was incomplete.

Eight per cent of nonvaccinated medical students who had no illness of any sort during the period of observation presented serologic evidence of recent contact with influenza A virus.

Vaccination with the complex vaccine of Horsfall, Lennette and Rickard appeared to induce the formation of complement-fixing antibodies in a certain proportion of persons.

The prophylactic value of this vaccine cannot be

determined from the data presented, since vaccination was undertaken at the inception of the epidemic. Eight persons, however, developed clinical influenza two weeks or more following vaccination.

## SYMPOSIUM: THE CONDITIONED REFLEX OF PAVLOV

### THE PHYSIOLOGIST'S POINT OF VIEW\*

ROY G. HOSKINS, M.D.†

BOSTON

IT is rather a large undertaking to present the fundamentals of the conditioned reflex or its more complex manifestation, conditioned behavior, in a few minutes. The doctrine of conditioned behavior is a relatively simple one, made up of only a few components but conventionally couched in a rather unattractive terminology. Conditioning can lead to such unexpected, bizarre and apparently illogical results that the hard-headed realist has some difficulty in admitting to himself that it represents sound biology.

To put the matter in everyday terms, I might stand at the ceiling and say, "Ugh." I should expect that procedure a primary unconditioned response of surprise,—but that I changed the syllable slightly to expect the reaction to be quite different. The syllable brings up a men-

tal image of the quadruped with fur who barks and becomes odoriferous when he is wet. To that second syllable, most human beings have been conditioned in a variety of ways, the end reaction being mostly mental imagery.

As another example of conditioning, I might guarantee, with two ounces of cellulose and a few grains of coal-tar derivatives, to produce in a man an increased pulse rate, deepening of the respiration and dilatation of the pupils—without having the materials within a hundred feet of the subject. The special circumstances would be that the subject, a lonesome American, traveling abroad, should suddenly come on "Old Glory" floating in the breeze. The conditioning, in this case, would have been due to the various experiences by which the citizen had learned the meaning of the American flag. "Learning" and "conditioning" are but two words for the same process. The learning, however, may include much more than the acquiring of conventional lore. It may

\* Papers were presented at the Section of Society, Boston, May 21, 1941.

cal  
otitis  
wer  
influe  
ompli-  
ants and

involve and be expressed by any active process in the body. In the flag example, the response involves smooth, cardiac and skeletal muscles.

The subject of conditioning is conventionally presented in terms that do not seem to mean a great deal. The classic example is ringing a bell and making a dog salivate—a happening seemingly remote from the field of practical pediatrics. However, for delineating the problem, I believe that the Pavlov dog can be profitably brought to the scene again. In Pavlov's earlier studies on the physiology of the digestive system, his experiments had been interfered with a great many times by the so-called "emotional reactions" of his dogs. About 1904, he decided to make a study of these confusing matters, and out of this study grew many years of work on conditioned behavior. One of his earlier procedures was to put some acid on the tongue of a dog and measure the resulting salivary secretion. Then, at the same time that the acid was given, a bell was rung, the procedure being repeated many times. After a while, the ringing of the bell alone caused increased salivation.

But essentially the same phenomenon is a matter of common experience. Ordinarily, when a man in his study hears the dishes in the kitchen begin to rattle, he is merely annoyed at the distraction. Suppose, however, he has been out skiing and is resting by the fire when he hears the noise from the kitchen; he suddenly realizes that his salivary glands are secreting, as are his gastric glands. So much, then, for conditioning of glandular functions.

Again, a man may be strolling down the street in the evening when a whiff of lilac perfume is wafted on the breeze. His higher brain may have lost all recollection of the pleasant evening in the moonlight years before by which the conditioning was established, but somewhere in the brain the trace has persisted and he reacts with a thrill of pleasure—in this case, perhaps a purely affective response, although with secondary somatic reverberations. Still enjoying the thrill, the man enters his home and sees the new maid looking sweet and attractive and has a little episode with her. The next morning, when the maid serves the breakfast, he gets red in the face. The conditioning this time expresses itself objectively via the vasomotor system.

A classic example of conditioning of still another sort is that of the boy who was given castor oil in canned peach juice. For fifteen years, he

could not taste peaches without nausea. But more than that, he also "tasted" castor oil each time. Here the conditioning was perceptual—a falsification of sense impression.

Another often cited case is that of Watson's baby, "Albert."\* The baby had had the benefit of a faultless environment up to the time he fell into the hands of the psychologist and had only two fears in the world—fear of loud noises and of falling—with which all babies are born. Watson put the baby on a table and then placed a rabbit beside him. Just as the baby reached for the rabbit, a steel bar was sharply struck behind his head. He started and drew back. The rabbit was brought up again, and just as the baby reached for it, the noise was repeated. This time, the baby drew back and fell on his side. The experiment was renewed (What the mother was doing in the meantime is not stated). Finally, every time a rabbit was brought near him, he went into a marked fear reaction: he cried, fell over and could not be induced with any sort of encouragement to touch a rabbit. Not only was he conditioned against rabbits, but his fear was generalized to include any kind of furry object—white rats, kittens, Santa Claus whiskers and so forth.

Such conditioned fears are of widespread occurrence and are of great clinical significance. Very often, the episode that caused the fear is not remembered, and the end result is called a phobia. Such phobias are seemingly utterly illogical, but they are very real and may go far to wreck the life of the patient.

In all the foregoing examples, the conditioning has been accompanied by awareness on the part of the subject. Such awareness, however, is not a necessary feature. By the simultaneous use of a sound signal and a flashlight, the pupils of a man can be conditioned to contract to an auditory stimulus, even when the subject is totally unaware of the purpose of the experiment and despite the fact that one has no voluntary control of the pupils. Unwitting conditioning of involuntary activities is probably a rather common happening.

So much for conditioning of positive responses. It is possible, and the possibility is clinically meaningful, also to set up conditioned inhibitions. For example, a dog may be conditioned to salivate when a point, X, on his skin is touched. He is then trained to discriminate between spot X and another spot, Y. Y becomes a so-called "negative spot." If Y is first stimulated and then X, no saliv-

\*This case is cited from *The Psychology of Adjustment* (Schafer, L. H. *The Psychology of Adjustment* 600 pp. Boston: Houghton Mifflin Company, 1936).

hospital personnel, but in a series of 91 pneumonia patients, serologic evidence indicating that a large number had had contact with influenza A virus suggested a possible relation between the two diseases.

Influenza A virus was isolated from 2 patients and was shown by serologic tests to be the chief etiologic agent in the outbreak.

No evidence for infection with influenza B virus was obtained, although certain patients with typical manifestations of clinical influenza gave no indication of a recent infection with influenza A virus.

The correlation between the clinical and serologic means of diagnosis was incomplete.

Eight per cent of nonvaccinated medical students who had no illness of any sort during the period of observation presented serologic evidence of recent contact with influenza A virus.

Vaccination with the complex vaccine of Horsfall, Lennette and Rickard appeared to induce the formation of complement-fixing antibodies in a certain proportion of persons.

The prophylactic value of this vaccine cannot be

determined from the data presented, since vaccination was undertaken at the inception of the epidemic. Eight persons, however, developed clinical influenza two weeks or more following vaccination.

## SYMPOSIUM: THE CONDITIONED REFLEX OF PAVLOV

### THE PHYSIOLOGIST'S POINT OF VIEW\*

ROY G. HOSKINS, M.D.†

BOSTON

IT is rather a large undertaking to present the fundamentals of the conditioned reflex or its more complex manifestation, conditioned behavior, in a few minutes. The doctrine of conditioned behavior is a relatively simple one, made up of only a few components but conventionally couched in a rather unattractive terminology. Conditioning can lead to such unexpected, bizarre and apparently illogical results that the hard-headed realist has some difficulty in admitting to himself that it represents sound biology.

To put the matter in everyday terms, I might say that the ceiling and say, "Ugh." I should expect that procedure a primary unconditioned look of surprise,—but that changed the syllable slightly to affect the reaction to be quite a different syllable brings up a men-

\* Papers were presented at the Section of Neurology, Harvard Medical School, director of the Harvard and Memorial Foundation for Neuro-

tal image of the quadruped with fur who barks and becomes odoriferous when he is wet. To that second syllable, most human beings have been conditioned in a variety of ways, the end reaction being mostly mental imagery.

As another example of conditioning, I might guarantee, with two ounces of cellulose and a few grains of coal-tar derivatives, to produce in a man an increased pulse rate, deepening of the respiration and dilatation of the pupils—without having the materials within a hundred feet of the subject. The special circumstances would be that the subject, a lonesome American, traveling abroad, should suddenly come on "Old Glory" floating in the breeze. The conditioning, in this case, would have been due to the various experiences by which the citizen had learned the meaning of the American flag. "Learning" and "conditioning" are but two words for the same process. The learning, however, may include much more than the acquiring of conventional lore. It may

cal  
othal.  
were  
influen  
ompli-  
ents and

ideal, and one is thus not surprised that these patients became conditioned to emotional settings, the one of fear and the other of rage.

May not the so-called "nervous element" in asthma be in large part conditioning—that is, a conditioned reflex? Examples of both certain and probable conditioned reflexes in the field of allergy are numerous and, to the initiated, easy of detection. One of our patients had asthma repeatedly in her own home,—in emotional environment,—whereas in a foster home a few miles away she never had an attack. Another girl had hives while at boarding school, but when she went home, they disappeared, they returned as soon as she boarded the train to go back to school. The cause of the original urticaria is not clear, but it was probably coincident with an emotion, possibly of homesickness, hence the conditioning. One may ask, "Assuming that you are right, and that this is a conditioned reflex of the skin capillaries, how shall we treat her?" The basic treatment should be not so much by calamine lotion, calicum or uncture of belladonna, but by avoiding the emotional reaction if it can be found. The woman sensitive to onions might respond merely from insight into the reflex, the girl with asthma accompanying fear, by obtaining reassurance, and the girl with asthma caused by rage, by intelligently thwarting the tantrums.

But one finds conditioned reflexes of the respiratory tract, when an element other than allergy is primary. The following case is duplicated in the practice of nearly every physician. The patient had an attack of influenza, early in January. Sinusitis and adenitis followed. Hemolytic streptococci were found. Fever lasted two or three weeks. Then the temperature became normal, and in February the child was sent back to school. She returned home with a "cold" that evening, then fever returned. Again, when she was better, she went to school. And again she got a "cold" and had another bout of fever. Once more, on returning to school, she was sick after only one day. The parents were distraught. Should she again return to school?

Does the child suffering from recurrent "colds" get a fresh virus infection each time she returns to school? Is she sensitive to school dust, sustaining each time a reflex irritation from such dust? Or, may she have a conditioned reflex to the school environment, where the first attack became manifest? The fever is a bit easier to explain, it was doubtless from the secondary invaders (bacteria of which the patient is a carrier), which became active as soon as the mucous membrane became reflexly engorged. The onset of each

recurrence was apparently conditioned, the course was guided by the secondary bacteria. A prolonged summer vacation, with changed environment, sunshine and warm weather, resulted in good health, and the patient became unconditioned. The next year's school session was passed without any infection, perhaps prophylaxis by a cold vaccine was given credit for the cure.

Another example is an adult patient who had continual recurrent infections one winter, the first attack was a virus infection, the others were characterized by swelling of the mucous membranes of the nose and throat (sinusitis?). Each attack followed a shopping trip to Boston.

Everyone is familiar with the people who get colds whenever they sit in a draft. The draft reflexly leads to mucous-membrane congestion. The proverbial contest between the persons who want the window open and those who want it closed shows that everybody does not experience this reflex. It is hard to believe that a virus comes in the window and picks out only certain people. Have these persons a conditioned reflex to the cold air, and does it refer back to the chill of an original influenzal infection?

A physician recently told me that he developed a pain in the muscles on the right side of the neck on exposure to a draft. It was definitely outlined as the sternocleidomastoid muscle. The pain was a soreness, as if the muscle were fatigued from overuse. There had apparently been a tonic spasm of the muscle, reflexly caused by the cold air. Was this a conditioned reflex? Did the conditioning date back to a spasm (torticollis) from a mild adenitis under that muscle?

Attacks of angioneurotic edema are very likely to be manifestations of a conditioned reflex. A leading scientist told me that he developed puffiness of the eyes and fullness of the throat when facing the stress of an important lecture.

About seven years ago, I read a paper before a Maine medical society on diarrhea in infants and children. I covered the causes of death—dehydration, toxemia, acidosis and inanition—and the treatment. At the end of the talk, one of the local physicians got up and said "You have told us nothing about nervous diarrhea. Why is it that when I get excited I have diarrhea?" In reply, I intimated that this was not common in children. However, I have thought it over a great deal since then. I now believe that nervous diarrhea is quite frequent in children.

We have all seen infants with summer diarrhea, those of us in pediatrics before 1920 have seen many. The baby gets diarrhea, it is starved, the diarrhea is checked. Then feeding is cau-

tiously resumed. Diarrhea tends to return, and nutrition is not maintained, although dehydration and toxicity are no longer present. If one observes these cases carefully, one may note movement of the bowels whenever the baby is fed, or whenever it is handled. Is this nervous diarrhea, peristalsis due to a conditioned reflex of the bowel muscles? Too often, the diarrhea returned when the patient was considered cured. Was this re-infection? Or may it have been conditioning? I recall one group of infants with summer diarrhea who persisted in having loose stools and malnutrition until January. Then all contracted measles, and were cured. Change of habits incident to the latter disease apparently unconditioned them.

If one has traveled a great deal in Europe, he will have consumed much sour cream and sour-cream ice cream. Two such travelers developed dysentery lasting three to five days. But every time ice cream was eaten over the next several years, a diarrheal movement shortly followed, with much of the pain and distress of the original dysentery but with no fever. One may therefore well ask, How many of our so-called "sensitivity-to-food episodes" may be conditioning rather than real allergic or toxic actions?

I recently had under my care a newborn baby. It was breast fed and had regained its birth weight at nine days of age. Then it developed loose stools—seven or eight a day—and stopped gaining. It had a stool every time it nursed. It appeared conditioned to have a stool every time it was fed; the nutrition was affected. To maintain nutrition, it was necessary to inhibit the reflex. Change of feeding habits or timing, bottle feedings, barium and bismuth were all considered. In this case, lime water gave relief.

In my own experience, a tendency for loose stools has on occasions been quite suddenly checked by a relatively heavy meal. A change of eating habits, type of food or time of eating seems occasionally to inhibit the hyperperistalsis. Does the banana or raw-apple feeding of diarrheal infants act to inhibit conditioned diarrhea?

Conditioning is apparent not only in diarrhea but also in habitual vomiting. One of my infant patients had been doing nicely until one day he vomited his orange juice; the next day, he also vomited his orange juice; other food had not been vomited. I recommended a change from orange juice to tomato juice, and the vomiting ceased.

The following story will be appreciated by those who have had to undergo intensive treatment with some of the new "magic" drugs. A ten-year-old patient had arthritis and tonsillitis. He was soon

receiving by physician's orders eight aspirin tablets, twelve sulfanilamide tablets, six yeast pills, four of vitamin B<sub>1</sub>, four of vitamin B<sub>2</sub>, four of nicotinic acid, eight of ascorbic acid and enough others to total fifty pellets a day. Each time, the pills went down harder and harder. By and by, it took half a glassful of water to down each pill. Gagging and occasional vomiting occurred. Anorexia followed. The sight of a pill was the sign for gagging, and conditioned vomiting was being established; when all pills were omitted, normalcy was restored.

The training of the infant in bowel habits is an application of the conditioned reflex. The youngster is placed on a chair, or pot, and a soap stick is inserted rectally. The irritation of the soap stick sets up rectal peristalsis, and the bowels move. The next day, the same procedure is carried out. The following day, just putting the child in his chair is sufficient to lead to rectal peristalsis, and the conditioning is accomplished.

The conditioning of the older child and the adult to regular bowel movements is much the same. But this conditioning can easily be broken if the patient makes a visit,—it is usually the "change of water," if one can believe what one is told,—if he oversleeps, as on a Sunday, if he is forced to share the bathroom facilities with visitors, or if he neglects the call of Nature.

It is now realized that the epileptic has some lesion in the brain or meninges that is the basis of the convulsive seizures. The actual attack is brought on by a reflex action originating elsewhere; these precipitating causes are numerous and include fatigue (eyestrain, poor posture), foci of infection, emotional reactions and constipation.

A few years ago, Dr. Frank Fremont-Smith<sup>2</sup> reported to the New England Pediatric Society the case of a young lady who had epileptic attacks on two different mornings after going on "blind dates." It was learned that she previously had become very much in love with a young man, and had been upset when he gave her up; she had met him while on a blind date. She died of a brain tumor six months later. The cause of the epilepsy was the brain tumor, but the convulsive attack was precipitated by the blind date. Another epileptic girl had an attack whenever she heard a loud or unusual noise, such as that caused by a falling kettle cover, by a boy falling from his bicycle or by a door slamming. The most frequently mentioned precipitating cause of an epileptic attack, however, is constipation. Is it due to autointoxication or conditioning?

In handling epileptic patients, one should con-

sider a conditioned reflex not as the cause of the brain lesion but as a possible factor in precipitating the attack.

Dentists see numerous cases of conditioning, resulting in syncope and diarrhea. Apprehension is undoubtedly the cause of the conditioning.

\* \* \*

With a recurrent complaint, such as upper respiratory infection, vomiting, diarrhea, allergic manifestation or convulsion, one should consider the possibility that a conditioned reflex has been established. A conditioned reflex may also be the basis of the onset of a bacterial infection. The so-called "nervous diseases" are frequently manifestations of conditioned reflexes.

One may rest assured, however, that not all conditioned reflexes are bad, any more than all habits are bad. Many conditioned reflexes are quite useful adjuncts to a normal and happy existence.

It is not particularly difficult to recognize that a patient's trouble is due to a conditioned reflex; it is often quite difficult to identify the causative stimulus, and even more difficult to remedy or inhibit the reflex.

One cannot help wondering if much of the relief from faith healing and from physiotherapeutic treatments is the result of inhibiting a conditioned reflex.

## CONDITIONED BEHAVIOR\*

GEORGE E. GARDNER, MD†

BOSTON

NOTHING intrigues the clinician more than a clinical case, and since I am today addressing men whose interests are primarily clinical, I shall outline as briefly as I can—and I hope more briefly than one would expect of a child psychiatrist—a case from which may come a realization of the importance of early life conditionings in the later personality deviations of childhood. It should be remembered that psychiatrists deal with complex pattern reactions rather than with the simple conditioned responses referable to one sign or symptom, and that I cannot give all the material—many times but slowly and painfully produced by the patient—that brings the conditioning factors into relief.

Frank, a 15-year-old boy, was referred to the Judge Baker Guidance Center by a welfare agency that asked for advice about disposition of the boy because he was a serious behavior problem at a trade school. According to the case record: "He has deliberately tried to undermine the authority of the teachers, is saucy and insubordinate, refuses to obey, and makes fools' of the teachers for the amusement of the other boys. He tries to attract attention by clowning, and tried to make himself out a 'tough guy,' telling such realistic stories about life at the Lyman School that people thought he must have been there. He has been in three foster homes before this school placement, showing the same reaction to authority and discipline in each, and he has particularly evidenced his hatred toward men who tried in the most friendly way to supervise him." He was discharged from the trade school, the day before I saw him, for insubordination and fighting with the masters.

Physical examination showed a good looking, well

developed youngster (above the average in height, and 13 pounds above the average in weight). He had no physical defects or disabilities, and the clinical history revealed that he had never been seriously ill. Two things were noted that were of interest later: he was very proud of his physique (flexing his muscles, expanding his chest), and he was well groomed and clean.

Psychologic examination showed the boy to be of average or better than average intelligence—he had an IQ of 117 on the Terman Test. He showed superior ability in work with concrete material, and hence one would have expected him to do well in trade training. He started school at 5 years, got A's and B's in the grades until his 12th year, when in the 8th grade he lost all interest in school, his marks dropped well below passing and he was not promoted. Inasmuch as most of the difficulties for which he was referred began at that time, one could tentatively say that the precipitating (but by no means causal) factor or factors presented themselves then.

A glance at the family history gave a suggestion of this precipitating factor. Frank was the eldest of three children. His father, although intelligent, was spasmodically employed as a skilled workman, for most of his married life, he had been cruel and abusive to his wife. He had one job after another, having little difficulty in finding work even during the depression years, but reportedly resigned his job at the least sign of authority on the part of his employers. He was thin, suffered from stomach trouble, and was nervous. The mother was described as "intensely neurotic, a poor manager." The home was poorly kept, and the children were allowed to run wild. Three years before I saw the boy, the precipitating event occurred: the home was broken up, a divorce followed, and the boy—after unsuccessful attempts to live first with the mother and then with the father—was taken over by a governmental agency. His four unsuccessful attempts at foster home living followed.

One would expect that this boy with such a background would welcome a good home, with love, security and a chance to gain the academic and vocational training that

\*Presented at the Section of Pediatrics, Massachusetts Medical Society, Boston, May 21, 1941.

†Assistant in pediatrics, Harvard Medical School, co-director, Judge Baker Child Guidance Clinic.

his own home would never allow him to experience. He was bright and attractive. What were some of the reasons for his inability to make an adjustment? Or better—for the purposes of this discussion—what were the conditioning factors in the first 12 years of this boy's life that made him a behavior problem for these 3 years?

The psychiatrist must look beyond the precipitating factors for the evidences of the conditioned responses, and he knows them to be varied, subtle and sometimes vague and symbolic, but he also knows that they are nonetheless effective and powerful. He looks for them principally in the relationships of the boy with each parent in turn, and specifically he seeks those individual traits, characteristics or patterns that the child has taken up from each parent and made a part of his own personality, and conversely he searches for that part of the parent that he rejects and hates. Believing these mechanisms to be couched best in terms of interpersonal relationships, the psychiatrist calls them identifications with or rejections of people or of any of the multivariates attributes of these most important people—the parents. The psychologist, presumably, calls them conditioned responses and inhibitions, and would say that the parents are the unconditioned stimuli that determine a child's response to people beyond the home ever after. Therefore, Frank's attitudes—his loves, hates and fears, and his acceptance or rejection of people—even extending to what Pavlov and Krasnorgorski call "generalization" to the most trivial attributes (the behaviorists would call them "elements") of various persons' faces, hair, clothes, occupations, hobbies and so forth,—all were largely based on his attitudes toward his parents woven into his behavior patterns in his very early years. Some of these points, as given by him to the psychiatrist, are briefly presented below.

In the course of the interviews, the boy gave many descriptions of his father and his feelings of hatred toward him long before the excesses leading to the divorce were in evidence. His father, of course, was the source of discipline in the family and was usually unreasonable in his demands. Moreover, he was more lenient with the other children, and his tendency to take their part in intrasibling rows and quarrels led Frank to develop strong feelings of jealousy of the siblings because of alleged favoritism. Frank particularly emphasized his hatred of his father's personal habits: his father did not keep himself, or his clothes, clean; he was slovenly, did not shave every day, took little or no care of his teeth, and seldom bothered to wear a necktie. The father was thin and withal he was frequently absent from meals, ate a poorly balanced diet, and drank and smoked cigarettes to excess. In brief, then, these are some of the characteristics of the adult man (the stimulus) that prompted responses of obedience from Frank for 12 very important years; many of these promptings were—as is so frequent in the arduous task of growing up—accompanied by (and hence associated with) various amounts of pain and resentment.

One is interested in the responses given by Frank to men other than the father who later asked that rules be followed and that chores be completed—or even to those adults whose interest in Frank was to help him without asking that he himself do anything in return. I must add, too, that during the time this material was

forthcoming he did not consciously associate his likes and dislikes with his father's personal habits or traits.

In the first place, the boy took a dislike to me, his physician, because I smoked and because I wore blue shirts (his father wore blue shirts). (I shall add, however, that I was not without a necktie, and that I was shaven and, I hope, passably clean.) He was quite careful to emphasize what he was not going to do, hoping to avoid any demands that I might wish to make of him.

In his first foster home, he stayed 2 weeks and then ran away. He described the home as dirty, and he stated that the foster father and foster mother "didn't bother to keep themselves clean, let alone the kids." (This accusation was not true.) He refused to do even the simplest and easiest tasks about the house, was arrogant toward the younger children, and bragged of his physical prowess and criminal exploits when he was trying to impress the older ones.

In the next foster home, everything went quite well for some months until the foster family took two other boys to board. Frank immediately accused the foster father of favoring the other two, and of making him do more than his share of the chores. He fought with these boys, would not allow them in his room, and refused to let them read the books that the foster father had previously bought for him. He finally became so surly and aggressive toward this foster father, whom he had previously liked, that he had to be removed.

In his school placement, he again did well for a short period, but soon his old patterns became evident, although at no time, as he later admitted to me, did any of the masters or fellow students initiate the quarrels. He was at a loss for an explanation of the fundamental cause of his antagonisms, but he readily gave what were to him their most outstanding characteristics. He scorned the younger pupils as babies who did not even keep themselves clean. He would not ride in the bus with them. (His siblings were both younger than he.) He fought with one boy continuously because he was "thin and anemic" (Frank always pictured himself as strong and powerful), and because he was "too well liked by the headmaster." One teacher he disliked because he knew he smoked and he suspected him of drinking alcohol. Another master, the athletic instructor, whom one would expect Frank to look up to and emulate, was an anathema because he was redheaded and had a mustache. (His father has reddish hair and a small mustache.) The shop instructor was sloppy in his habits, did not clean his fingernails, and wore blue denim shirts, open at the neck.

In a temporary home placement, the boy carried over his hatred of the school's athletic instructor to his new foster parent, who happened to be a coach in a nearby college. He admitted that he liked this man at first, but after a reprimand for not helping in the household tasks he took a strong dislike to him and consciously equated the two men in personality and attitudes.

One could add many more instances wherein this boy's reactions to people, and particularly to those in authority, were conditioned (sometimes by association to the minutest details of physique and habit) by his responses to and feelings about the first and most impressive authority-stimulus in

his life, his father I have, of course, not commented on his feelings about his mother or the patterns predicated thereon, but they are quite as interesting and instructive

Treatment of this boy entails a long time process of reconditioning. He must, with assistance, gain insight into the varied and subtle ways by which this initial pattern reaction to his parents and sib-

lings is reactivated with such disastrous results in later and other situations entailing adults and children who are not his parents and not his favored siblings—even though they may have a few elements or attributes in common. In the terms of Pavlov, he must learn to differentiate the people who stand before him as stimuli.

38 Beacon Street

## POST-PARTUM CARE\*

### Preliminary Report of Studies in a Follow-Up Clinic

C WESLEY SEWALL, MD,<sup>†</sup> AND OWEN C MULLANEY, MD<sup>‡</sup>

BOSTON

POSTNATAL care is not new in the true sense of the word, and yet in years past, the application of this care has been indifferent and, in general, without sufficiently close supervision to be of any value, either to the patient or to the physician.

One of us (C W S), after close supervision of his own private cases for a period of years, has been impressed by the fact that it would be just as practicable to administer this same care to house cases. Prenatal care is now highly developed and specialized. Why should not postnatal care, which is just as important although not so well recognized, be carried out in the same painstaking manner? It is our opinion that insufficient time is devoted to that part of the post partum period when most of the serious, persistent and chronic conditions of the postparturient woman present themselves.

In most postnatal clinics, patients are discharged six weeks after delivery, unless unusual complications are present. This, we believe, is a serious error because, as previously mentioned, many of the conditions that adversely affect the patient's future life occur after this period. Moreover, a follow up of this period furnishes excellent clinical material for the instruction of medical students, interns, residents and junior staff members. Greenhill<sup>1</sup> advocates the follow up of the postnatal patient for one year and predicts that, if as much care is given after delivery as prenatally, untold misery will be avoided—such as cancer of the genital organs, a high incidence of which is found even in well run clinics.

Accordingly, we decided on a program of examining patients routinely six, twelve, twenty-four and forty-eight weeks post partum, and at as many

other times as each case seemed to require. This procedure has been carried out for only a year, and this is therefore merely a preliminary report.

One of the problems was to impress on the patients the value of our follow up of one year. Enlisting the aid of the Social Service Department, we decided on preparing three form letters: the first letter, which was given to the patient while she was in the hospital, explained our plans and made the first appointment (six weeks after delivery); the second letter, which was sent if the patient did not keep her appointment, gave another date, the third letter, which was sent if the other two were disregarded, asked the patient to come to the clinic on the next clinic day. If she then failed to appear, she was removed from our active file. We also enlisted the aid of the Community Nursing Association, which first undertook the follow up work on a basis of trial, however, the results were so successful that the association has undertaken the problem as a regular function for the coming year.

It has been our practice to have the house staff of the previous three months take over the postnatal service for the following three months, supervise the work of the residents and interns, make suggestions and confirm diagnoses. In addition, the third year and fourth year medical students at Boston University School of Medicine attend in the capacity of observers. The advantage of this system is that the same men who treat the patients have the opportunity to follow them in the postnatal period.

The house and district obstetric services of the Massachusetts Memorial Hospitals comprise yearly 700 to 900 patients, of whom about 500 to 600 are delivered in the hospital and 150 to 200 on the district. On discharge, both house and district cases have a routine obstetric summary and physical examination according to a special

\* Massachusetts Memorial Hospitals

<sup>†</sup> Assistant in Obstetrics Boston University School of Medicine

<sup>‡</sup> Assistant in Obstetrics Massachusetts Memorial Hospitals

form, which is forwarded to the postnatal clinic and filed with the record. All patients are instructed in routine exercises and also in the daily practice of vinegar douches in an attempt to restore the normal pH of the vagina; furthermore, they are advised to continue taking iron until the first postnatal visit.

Of the 631 house deliveries for 1940, 482, or 76.5 per cent, returned for a total of 1617 visits. These clinics at first averaged about 24 patients a week for a given month, but gradually grew to average as high as 41. For the year,

TABLE 1. *Census of Postnatal Clinic.*

MONTH	NO. OF ADMISSIONS	NO. OF RE-ADMISSIONS	NO. OF NEW PATIENTS	AVERAGE NO. OF PATIENTS PER WEEK
January	98	72	26	24
February	118	96	22	24
March	151	109	42	38
April	125	95	30	31
May	120	69	51	30
June	163	95	68	41
July	117	80	37	39

September	128	91	37	32
October	190	146	44	36
November	100	68	32	33
December	131	98	33	33
Totals	1617	1135	482	33

the average was 35 patients, the largest number reporting in June and July, possibly owing to summer vacations. Table 1 shows the growth and monthly variation of the clinic.

Subinvolution

Subinvolution was found in 15 cases. The diagnosis was established on the finding of a large boggy uterus, subjective symptoms and bleeding. A uterus that is not contracted below the symphysis at six weeks was considered to be subinvolved, the fact that multiparity influences the uterus being considered. Twelve cases had no associated symptoms. Three cases had associated bleeding, which was not severe. Hot prolonged douches completed the involution in all these cases. The patients were mostly multiparas with large families who obviously were neglectful in obtaining rest and proper hygiene.

Procidentia

Procidentia was found in only 3 cases; of these, 1 was first degree, and 2 were second degree. Since all these patients were in the childbearing period without symptoms, no treatment was considered necessary. It is our opinion that treatment of this condition should be influenced by the severity of the symptoms and the discomfort experienced. Atlee<sup>2</sup> advocates treatment before late years and before more serious trouble sets in if the patient has symptoms. If, after repair, subsequent labors

are well managed and enough time is allowed to elapse after operation, there should be no ill effects.

Retrodisplacement

Retrodisplacement of the uterus was found in 307 cases, or 60 per cent, and of these patients only 28, or 8 per cent, showed symptoms. Manual replacement, with insertion of a pessary, was tried in all cases with symptoms. Those patients in whom the pessary cured the symptoms, but who did not remain symptom free with removal of the pessary, were referred to the Surgical Service for operation. If the uterus returned to its posterior position without symptoms, once the pessary was removed, we did nothing. We do not believe that a uterus should be replaced anteriorly if the patient is symptomless. DeLee and Greenhill<sup>3</sup> state that exercise for uterine replacement, except in the immediate post-partum period, is worthless. This has also been our experience in the clinic.

Lacerations

Cervical lacerations were observed in 174 cases, or 36 per cent: these were divided into 80 unilateral, or 46 per cent, and 94 bilateral, or 54 per cent. Most cases found were in multiparas, and the degree of involvement was proportional to the number of pregnancies.

Erosions

The commonest complication found in the clinic was erosion, with or without endocervicitis. The erosions were classified as slight, moderate or marked, depending on whether a small or large part of the portio or canal was involved. Slight erosions were found in 225 cases, or 44 per cent, moderate erosions in 56 cases, or 12 per cent, and severe erosions in 34 cases, or 7 per cent, for a total of 315 cases, or approximately 63 per cent of all cases examined.

Matthews<sup>4</sup> states that the etiology of these erosions is trauma, with associated infection, and that the commonest organisms are the streptococcus, staphylococcus, gonococcus and colon bacillus. The gonococcus and staphylococcus are the most frequent offenders. Matthews tells how the columnar epithelium, because of the constant stimulation of infection, pushes out into the vaginal portion of the external os, replacing the stratified squamous epithelium common to this area. Hypersecretion of the glandular structures, if these are obstructed, goes on to the formation of nabothian cysts. Therefore, an erosion is not an ulceration but a new formation of glandular tissue. Wollner<sup>5</sup> states that these changes can be produced by unopposed action of estrin. He be-

lieves that endocrine imbalance is responsible for the production of these erosions. Roblee<sup>6</sup> attempts to show that vaginal pH is the cause of these erosions, and that a cervix with a pH of 6.5 to 7.5 shows columnar proliferation. A report of the Central Association of Obstetricians and Gynecologists<sup>9</sup> reveals that birth trauma is the most significant factor in erosion and endocervicitis. Barrett<sup>7</sup> states that cervical injury occurs in the majority of vaginal deliveries, and that, if they do not heal, these lesions favor the future development of chronic endocervicitis and hypertrophy and may be the source of serious pelvic disease. Fulkerson<sup>8</sup> considers the trauma of abortion or labor to be the cause, and believes that the infective organism is seldom the gonococcus.

In the literature, erosion and endocervicitis have been found to be the cause of leukorrhea, backache, occasional menstrual disturbances, urinary symptoms, sterility and a hearing down or dragging sensation in the pelvis. The value of treating these lesions early is emphasized by Matthews,<sup>1</sup> who states that "the new gland tissue may become malignant under certain conditions." He also shows that there is slight difference between the orderly arrangement seen in cystic hyperplasia and endocervicitis and the disorderly arrangement, with embryonal cells, found in true neoplasia. Moench<sup>2</sup> declares that the infected cervix may become a focus in chronic arthritis.

The popular methods of treating these erosions and endocervicitis appear to be by caustics, electrocoagulation, cautery, conization and the Sturmdorf operation. The controversial attitude of older writers is changing gradually, and more recent work tends to support electrocoagulation and conization. Fulkerson<sup>8</sup> states that caustics and antiseptics are only palliatives and rarely curative, and recommends the use of the cautery. Frost<sup>10</sup> advocates electrocoagulation not only of the postpartum cervix but also of the prenatal cervix from the sixth week to the fifth month. Much could be said for and against this statement about the prenatal cervix, but we are in agreement with the statement regarding the postnatal cervix. Miller and Todd<sup>11</sup> advocate conization for the more extensive benign lesions of the cervix and say the conization will completely replace the Sturmdorf operation. Greenhill<sup>1</sup> states that conization will accomplish as much as the Sturmdorf operation without the expense or inconvenience of the latter operation. Stadium<sup>12</sup> condemns cauterization of the cervix because this procedure does not allow microscopic study of the whole or part of the cervical tissue. Zelezny-Baumrucker and Baumrucker<sup>13</sup> are in favor of electrocoagulation to

promote healing and stop leukorrhea. Jacoby<sup>14</sup> states that cauterization with electricity is the method of choice because cervixes heal faster with this than with other methods. Electrosurgery is contraindicated in women in the childbearing age and pregnancy, and in those with acute cervical involvement, and acute and subacute tubal involvement.

In our clinic, we have investigated 100 cases of erosion and mild endocervicitis, which we have coagulated, and 25 cases of marked erosion and endocervicitis with cyst formation, which we have coned.

We believe that some cases of erosion may be due to endocrine influence, but that this complication generally appears late in pregnancy and is completely healed about six weeks post partum. These erosions are often found in the prenatal clinic, and become so severe that the possibility of placenta previa has to be ruled out because of vaginal bleeding. They typically show the heaped-up advance of rapidly proliferating columnar epithelium invading the portio. This picture is consistent with Wollner's<sup>5</sup> theory of "estrogenic stimulation," causing erosion. On discharge two weeks post partum, some cervixes show little evidence of former endocervical hyperplasia, which is consistent with the return of the estrogenic level to normal post partum levels.

The influence of the pH of the vagina in causing and healing these erosions is uncertain. The statement of Roblee<sup>6</sup> that the factor of the lowered pH is the causative agent in erosion cannot be denied or confirmed by our observations. However, that a lowered pH is an essential requisite in the healing of this type of lesion cannot be denied. The spontaneous healing of many mild erosions that exist beyond the immediate post partum period can be explained on these grounds. For this reason, we routinely prescribe acid douches after delivery as an aid in preserving an acid medium.

In agreement with most authors, we believe that the trauma of labor and infection play the leading roles in the causation of these conditions. Of 100 cases selected from our service, we found that the average parity was three and the average time that elapsed before treatment was nine weeks post partum. We believe that the majority of these mild erosions and hyperplastic lesions that are seen in the first six weeks post partum heal spontaneously. For that reason, at the first postnatal visit, we are conservative in our estimation of cervical disease. If an erosion is present, these patients are asked to return weekly for observation. If healing is not prompt, more vigorous therapy

is instituted. In these early cases, caustics, such as silver nitrate, probably have little value. The earliest case that we coagulated was eight weeks in duration, and the oldest was one year. Of these 100 cases, we classified 17 as slight, 50 as moderate, and 23 as marked. Discharge was the chief complaint in 46 per cent, and bleeding, traumatic or otherwise, was encountered in only 5 per cent. No case was coagulated if there was any evidence on bimanual vaginal examination of tenderness suggesting infiltration or other signs of pelvic infection. Twenty of these cases had previously been treated with silver nitrate, some as long as six months. This only helped to convince us of the worthlessness of this method. The average surface-healing time for this series was five weeks. This is much shorter than that reported by Jacoby,<sup>14</sup> unless he refers to complete capillary obliteration. In this series, we had failures in only 2 cases; one, we believe, should have been coned, and the second was not coagulated deep enough but, when recoagulated, healed in six weeks. Four per cent of our patients treated by coagulation became pregnant before they were discharged from the clinic.

There were no cases of activated pelvic inflammation, probably because, as previously mentioned, no case that showed the slightest evidence of pelvic inflammation was coagulated. We have followed 50 cases for three and 17 for six months, with no recurrence.

In the 25 cases of marked erosion and endocervicitis, the therapeutic method of choice was electroconization. The indications for conization, differing from coagulation, were as follows: profuse discharge, uterosacral tenderness, backache attributed to uterosacral infiltration, edema, hyperplasia of the cervix and severe cervical laceration.

Patients were instructed to report for appointment the day that they started menstruating, and to come in to the hospital usually two or three days postmenstrually without breakfast. Pentothal intravenously or nitrous oxide and oxygen was the anesthetic of choice. After coning, the bleeders are coagulated and, if necessary, are sutured. Sutures are also used to reconstruct the cervical canal if extensive plastic measures with the coning knife are necessary. After operation, the cervical canal is packed with iodoform gauze, and the vagina with vaseline gauze. Both packs are left in situ for three days. After removal of both packs, douches are begun daily. If the pH is kept low, there will be less bleeding, and any sutures used will hold better.

The average parity in these cases was four; the time post partum was eighteen weeks. Backache

was found in only 4 cases, about 16 per cent, and we noted that in general the symptom is oftener one of orthopedic than of gynecologic origin. Half the cases showed nabothian-cyst formation—evidence of long-standing infection. One case showed an epithelioma (Grade III), which the pathologist thought was completely removed. The patient was treated with radium and x-ray promptly, and is still under observation. Two cases exhibited polyps that on microscopic examination proved to be benign. The average time required for surface healing was six weeks.

We followed 14 of these 25 cases for three months and 7 for six months. There were no poor results or recurrences, and the patients were free of symptoms on subsequent examination. We encountered bleeding in only 1 case postoperatively; that was two weeks after coning, and the bleeding was probably traumatic in origin.

We have not as yet followed any of these cases through pregnancy, but one of us (C. W. S.) has followed private cases through two or three pregnancies, with no evidence of dystocia or tendency to abortion. There frequently appears to be a narrowing of the cervical lumen at six to eight weeks. This is a simple exuberant proliferation of epithelial cells. At ten to twelve weeks, the same canal is widely patent, owing to recession of the tissues and the disappearance of edema. To date, we have had no cases of stenosis or abortion.

We believe that conization is the therapy of choice in this type of case, but that it should be performed in the hospital under anesthesia, because of the danger of severe bleeding. Furthermore, this procedure allows a thorough examination to be done on the cervix and ample time to destroy all nabothian cysts. The use of excessive current destroys tissue for the pathologist and causes excessive slough, which may be followed by bleeding. Conization is an excellent method of cervical biopsy, by which many cases of unsuspected cancer may be discovered, and it does not cause dystocia or stenosis.

### *Anemia*

Only 2 cases of anemia were encountered post partum; they were both of a dietary nature and responded to diet and iron therapy. This condition may be eliminated if the patient is instructed in taking some type of iron preparation during the first six weeks following delivery and if a proper diet can be followed.

### *Perineal Relaxation*

In the hospital, the use of perineotomy is routine in all primiparas and also in multiparas when

indicated. The benefit of this practice can best be seen in that only 4 cases showed poor perineal support.

Only 2 cases of secondary repair, both in the recent post-partum period, were performed in the hospital. One was especially interesting in that a vitamin C determination showed the patient to have subclinical scurvy. After treatment with vitamin C, the patient was repaired and promptly healed. The other was a case of infection, which broke down.

### *Cystocele and Rectocele*

Slight degrees of cystocele and rectocele were found in many cases. However, only 30 severe cases of cystocele, or 6 per cent, and 21 marked cases of rectocele, or 4 per cent, were discovered. This is a very small number, when one considers that many of these were found in women who had had many pregnancies and who had been delivered at home.

Cystocele and rectocele in slight degree appear to be the end result of almost all deliveries by the vaginal route. We believe that prophylactic forceps delivery and perineotomy as routine procedures greatly reduce the severity of these complications. We also think that great damage may be done to the pelvic tissues, even where there is no external laceration.

### *Infections*

No proved cases of gonorrhea or trichomonal infection were observed, but there were occasional cases of infection by monilia. In consideration of the number of examinations done, this is rather remarkable. Greenhill<sup>1</sup> states that no pathogenic organism except monilia can exist in a medium below a pH of 5.

### *Nonobstetric Diseases*

A very short time had elapsed before we realized that we should find many conditions in these women that would be beyond the scope of our clinic. This required the reference of 137 cases, or 27 per cent, to other clinics for treatment. Appreciating that cases involving the kidneys should be more closely followed than the average patient, we established a close link up with the genitourinary service, and cases were jointly followed in detail. We hope in the future that this study will be a source of information and research, and that lessons of value will be deduced. At the present time, the follow up of this type of case in the remote post partum period seems to be neglected. Table 2 shows the distribution of cases referred to other clinics. Two cases referred to the surgical and genitourinary services are of special interest.

The patient in one case complained of pain in the left lower quadrant for which no apparent cause was found; this was when she was about five months pregnant. The pain became severer when the patient walked or arose from a sitting position, and did not radiate. During the post-partum period, a mass was found in the left

upper abdomen. The pain, although not constant, became severer at times. There were no genitourinary or gastrointestinal symptoms or loss of weight. At operation, a large ovoid shaped, moderately movable mass was found; it was 15.2 cm. in length and 8.9 cm. in width, extending from the upper border of the left broad ligament to within 2.5 cm. of the lower pole of the left kidney. The peritoneum over the tumor was thickened and edematous, with the appearance of an inflammatory mass. The mass was found to contain old chocolate colored blood. The diagnosis of a retroperitoneal hematoma was made. The etiology of the hematoma could not be proved, and there was no history of trauma.

The patient in the other case complained of pain in the left hip and left lower quadrant for a year; it had become worse during pregnancy. After delivery, the patient was followed in the post-partum clinic, where a pelvic mass was found. The diagnosis of ectopic kidney was made. The kidney was removed, and the patient made an uneventful recovery.

### SUMMARY AND CONCLUSIONS

Nearly 500 obstetric cases were followed for as long as one year post partum. The results indicate that prolonged and intelligent post partum care is extremely valuable in preventing, discovering and properly treating the sequelae of delivery.

The commonest complication after delivery was erosion, with or without endocervicitis. The causes of the erosions may be divided into endocrine, chemical and traumatic associated with infection. Coagulation and conization are the methods of choice in treating these lesions. The latter is a hospital procedure, and should be performed under

anesthesia. Coagulation and conization should never be done if there is any evidence of pelvic infection.

Rest and proper hygiene are essential for proper involution of the uterus. Retrodisplacement of the uterus, without symptoms, is normal in many cases. If symptoms are found early in the postpartum period, manual replacement and the insertion of a pessary comprise the method of choice for treatment. Surgery may be resorted to if the condition is unrelieved by these methods.

If there are symptoms, procidentia calls for surgery.

Prophylactic forceps delivery and perineotomy, if necessary, prevent much damage to the pelvic tissues.

Cases involving the kidney should have more intensive and specialized follow-up.

Backache is oftener orthopedic than gynecologic.

MEDICAL PROGRESS

CARDIOLOGY: I. CHEMOTHERAPY IN HEART DISEASE.  
II. THE FALSE DIAGNOSIS OF ORGANIC HEART DISEASE\*

HERRMAN L. BLUMGART, M.D.†

BOSTON

I. CHEMOTHERAPY IN HEART DISEASE

THE striking therapeutic successes achieved by the sulfonamide compounds in a variety of diseases have led naturally to the trial of these substances in the treatment of various diseases of the cardiovascular system. Sufficient time has elapsed to make it profitable to review and evaluate the results obtained to date in the chemotherapy of heart disease.

Rheumatic Fever

Hopes that the sulfonamide compounds would exert a favorable effect on active rheumatic fever have not materialized.<sup>1,2</sup> As pointed out in a previous communication,<sup>3</sup> convincing studies have demonstrated no beneficial effects on chorea or on active rheumatic infection in any of its stages. On the contrary, the incidence of toxic reactions to these drugs is apparently increased, and the

clinical course of the illness seems to be adversely affected. When patients with rheumatic heart disease suffer from acute streptococcal tonsillitis, conservative clinical judgment must be exercised about the advisability of administering a sulfonamide compound, particularly since it is the impression of some observers that latent rheumatic infection may be activated by such chemotherapy.<sup>1</sup>

Several studies<sup>4-6</sup> have been made to determine whether sulfanilamide administered prophylactically to patients in the latent phase prevents recrudescences of acute rheumatic fever. It is recognized that recurrences and exacerbations are often associated with upper respiratory infections. It therefore seems reasonable that the prevention of hemolytic streptococcus infections may prevent these rheumatic recrudescences. Thomas and her associates<sup>6</sup> have recently reported the results of a four-year study. Sulfanilamide was given continuously from October or November until June to 55 patients with recent histories of acute rheumatic fever during 79 person-seasons between 1936 and 1940. Sixty-seven patients with a similar history who were given no prophylactic treat-

All articles in this series will be published in book form: the current volume is *Medical Progress: Annual, 1940* (Springfield, Illinois: Charles C Thomas Company, 1941. \$4.00).

\*From the Medical Service, Beth Israel Hospital, and the Department of Medicine, Harvard Medical School.

†Associate professor of medicine, Harvard Medical School; visiting physician, Beth Israel Hospital.

ment were observed simultaneously during 150 person seasons. Major rheumatic recrudescences did not occur in those receiving sulfanilamide prophylaxis, but major attacks of acute rheumatic fever in 15 patients and the development of subacute bacterial endocarditis in 2, resulting in 4 deaths, occurred in the control group. Twenty grams of sulfanilamide was administered daily, divided into two doses taken twelve hours apart. The toxic effects from this prolonged dosage with sulfanilamide were negligible. Encouraging results from similar prophylactic treatment have recently been reported by Coburn and Moore.<sup>1</sup> Infections of the throat were prevented, and rheumatic recrudescences did not occur. These authors who used somewhat larger daily doses of sulfanilamide, namely 30 to 45 gr., noted toxic symptoms in approximately 10 per cent of the treated subjects. The incidence of rheumatic fever in their group of 184 children over a three year period was less than 1 per cent, whereas the expectancy according to the control group was 35 per cent. After the onset of streptococcal pharyngeal infections, administration of the drug did not prevent rheumatic recrudescences.

These encouraging results offer hope that further studies in larger groups by various investigators will provide the basis for an additional method with which to combat rheumatic fever.

#### *Subacute Bacterial Endocarditis*

Until recently, all treatment of subacute bacterial endocarditis has been considered generally ineffective. The use of the various sulfonamide compounds—either alone or combined with hyperthermia, heparin, radiation or intravenous typhoid paratyphoid vaccine—has naturally aroused wide spread interest. In an evaluation of the results of therapy of this condition, three essential criteria must be satisfied: the diagnosis of endocarditis must be established with reasonable certainty, the incidence of spontaneous recovery must be used as a comparative basis, and variations of the virulence of certain infections from year to year must be considered. That spontaneous remissions of the disease and even recovery may occur is evidenced by the reports of various authorities. The most favorable outlook for spontaneous recovery from subacute bacterial endocarditis is contained in publications by Libman.<sup>8,9</sup> He differentiated the so-called "bacteria free" and "recovery" cases, employing the former term to designate those cases in which the bacteria had disappeared but sequelae were present, and the latter to indicate the disappearance of the infection without any residual clinical evidence except the

valvular defect that might be present. He noted full recovery in about 3 per cent of the patients in the usual form of the disease running a course of four to eighteen months or more. In a later report,<sup>9</sup> Libman enumerated 12 recoveries in a total of 1000 cases. Three per cent probably represents, therefore, the most optimistic incidence of spontaneous recovery. In 200 cases collected from the literature and from the records of the Mt. Sinai Hospital in which the sulfonamide drugs were administered, recovery occurred in 6 per cent.<sup>10</sup> In much smaller groups of cases in which chemotherapy was combined with heparin, hyperthermia or other measures, the recovery rate was somewhat higher. The number of cases was too small, however, to yield conclusive results. In general, it appears that all the combined methods of therapy have as their effective agent the sulfonamide compounds. Indeed, untoward complications such as embolism and cerebral hemorrhage seem somewhat more prevalent in cases treated by the combined methods.<sup>11-13</sup> Present information permits no definite statement regarding the sulfonamide drug of choice. Sulfathiazole, if it is well tolerated, is effective with unusual organisms as well as with *Streptococcus viridans* and nonhemolytic streptococci and is evidently somewhat preferable to sulfanilamide and sulfapyridine. Information regarding the usefulness of sulfadiazine, which has been recently introduced, is meager, but the report by Finland and his associates<sup>14</sup> is not encouraging. They obtained negative blood cultures after treatment in only 1 of 5 cases, in the others, the bacteremia persisted in spite of continued therapy. At the time of their report, 1 patient was still under treatment, the other 4 having died.

The generally disappointing results of chemotherapy in subacute bacterial endocarditis, despite the not infrequent negative blood cultures obtained following administration of the drug, are made understandable by the work of several groups of investigators,<sup>15-17</sup> who have studied the bactericidal effect of the sulfonamides on various strains of streptococci under various conditions of growth in vivo and in vitro. Human blood clots suspended in solutions of sulfanilamide, sulfapyridine, sulfathiazole and sulfamethylthiazole for periods of one to fifteen days do not show any appreciable penetration by the drug. Even in those cases in which the drug is actively bactericidal for the causative organism, the layer of fibrin acts as an impenetrable barrier. As Duncan and Faulkner<sup>17</sup> have pointed out, this does not necessarily signify that complete eradication of the infection is theoretically impossible. In the

course of time, all the pre-existing thrombi could be organized into fibrous scar tissue, and all newly formed thrombi in a patient under active treatment would be impregnated with the drug. The conditions will tend to become less and less favorable for the growth of the organism, if an effective drug is taken continuously for a long time. Subacute bacterial endocarditis, however, is unlike the ordinary infection caused by a hemolytic streptococcus. It is primarily a focus of growing, relatively avirulent streptococci in a fibrinous platelet mass, which not only completely isolates the organisms contained within it from the living tissue of the body, but may also act to prevent them from coming in contact with any particular chemical substance introduced into the blood stream. The small number of reported recoveries is therefore not surprising.

To summarize, the incidence of recovery following the use of sulfonamide therapy warrants its application in cases of subacute bacterial endocarditis, and the earlier the treatment is instituted, the better presumably are the chances for cure.<sup>18</sup> The evidence for increased therapeutic value in combining sulfonamide therapy with other agents is not sufficiently impressive to indicate the use of the latter, particularly since untoward complications may be thereby introduced and may involve additional expense and hardship to the patient. In a large proportion of the cases treated with sulfonamide compounds, blood cultures become negative, and clinical improvement, reflected by lowering of the temperature and heart rate and increased sense of well-being on the part of the patient, may occur only to be followed by relapse. The antipyretic action of some of the sulfonamides must be borne in mind.<sup>19</sup> If one of the sulfonamides is poorly tolerated or is ineffective, one of the other preparations should be utilized. In some patients who recover, not only do the usual clinical signs of activity disappear, but the sedimentation rate returns to normal.<sup>16</sup>

#### *Prophylactic Use of the Sulfonamide Drugs in Relation to Endocarditis*

Many readers will have noted in their own experience—and this impression is further strengthened by case reports in the literature—the association of recent tooth extraction, tonsillectomy or upper respiratory infection with the onset of endocarditis. It is consequently of great interest to note the finding of Fischer and Gottdenker<sup>20</sup> of positive blood cultures within two hours after uncomplicated tonsillectomy in 21 of 64 cases. Blood cultures obtained preoperatively and from

twelve to twenty-four hours after operation were uniformly negative. Of 18 cases in which nasal operations were performed, 2 showed transient bacteremia.

Palmer and Kempf<sup>21</sup> report the presence, usually in pure culture, of *Streptococcus viridans* in more than 90 per cent of extracted teeth from which cultures were taken. They also obtained blood cultures on 82 patients who had dental extractions under local anesthesia; in no case were more than two teeth removed. Negative cultures of the blood were obtained in all immediately before operation, whereas 14 of the 82, or 17 per cent, showed positive blood cultures immediately after the extractions. In 13 of the 14 patients with positive cultures, the blood was sterile ten minutes later. Transient *Streptococcus viridans* bacteremia has been observed after dental extractions by other investigators<sup>22</sup> in approximately the same percentage of cases.

These observations suggest that, in patients with pre-existing rheumatic valvular lesions or congenital defects in the heart, localization of the organisms on the lesions during transient bacteremia may initiate the bacterial endocarditis. The frequency with which sulfapyridine or sulfadiazine produces negative blood cultures in patients with subacute bacterial endocarditis raises the question whether a sulfonamide drug should not be administered before operative procedures in patients who are particularly susceptible to endocarditis, that is, persons with congenital heart disease or healed rheumatic valvular disease with normal rhythm and no signs of congestive failure.

#### *Acute Endocarditis*

Although recovery from simple gonorrheal bacteremia is not uncommon (indeed a transient bacteremia probably occurs in every case of gonococcal arthritis), spontaneous recovery from proved gonococcal endocarditis is extremely rare. Only 3 examples of proved cases with recovery were cited in 1939 by Futcher and Scott.<sup>23</sup> Newman,<sup>24</sup> in 1933, and Davis,<sup>25</sup> in 1940, also reviewed the subject. Since sulfanilamide and the related chemotherapeutic compounds have been shown to be effective in the treatment of gonorrhea, these drugs have been administered to patients with gonococcal endocarditis. The recent reports of such cases, with recovery after treatment with sulfonamide compounds,<sup>23, 26</sup> although not conclusive, warrant further trials of the therapeutic efficacy of these drugs. Acute endocarditis due to staphylococci, meningococci or pneumococci almost invariably results in death, even though bacteremic cases without endocarditis may respond favora-

bly.<sup>14, 27, 28</sup> The earlier the treatment with sulfonamide compounds is begun in these conditions, the more favorable are the chances for recovery.

## II. THE FALSE DIAGNOSIS OF ORGANIC HEART DISEASE

Cases are not uncommon in which the false diagnosis of heart disease has led to serious if not tragic consequences. Such errors are due to the fact that it is usually easier to be certain of organic heart disease on the basis of definite pathologic findings than it is to be certain that no disease is present when the findings are equivocal.<sup>29</sup> Parkinson<sup>30</sup> has called attention to the danger of making a definite diagnosis of heart disease on the basis of such findings, stating, "A shaky sign is a poor foundation for a weighty diagnosis." The induction of thousands into the armed forces has naturally led to increased interest regarding the significance of various symptoms and signs.<sup>31-33</sup> Hence, it seems appropriate to review the significance of the equivocal signs and symptoms of cardiac disease in otherwise normal persons; the effect of pathologic conditions on the heart, such as endocrine disorders and nutritional states, will not be discussed.

### *Sinus Arrhythmia*

The decided phasic slowing of the heart beat with respiration, that is, sinus arrhythmia, may be noted by anxious patients or their relatives. It is usually asymptomatic, occurs particularly at the extremes of life in the young and the aged, and is of no pathologic significance.

### *Bradycardia*

Cardiac rates as low as fifty are found not uncommonly in young athletes; but, in contradistinction to the bradycardia of heart block, the cardiac rate rises in a normal manner on effort. Such observation of the cardiac rate on exercise will usually establish the diagnosis. Similar slowing of the heart may be observed after acute fevers.

### *Premature Contractions*

Premature auricular or ventricular contractions not infrequently lead the apprehensive patient to seek medical advice; the more stolid may be completely unaware of their presence. In the absence of other evidence, these irregularities should not be considered to indicate heart disease, for they may be found in hearts otherwise completely normal. In aging persons previously free of such abnormality, regularly recurring extrasystoles may, however, be an early indication of coronary arteriosclerosis. The etiologic role of coffee, tobacco and

alcohol in these disturbances should always be considered.

### *Paroxysmal Auricular Tachycardia*

Paroxysmal auricular tachycardia, with its abrupt onset and offset, and its absolutely fixed regularity at rates of 150 to 200 or even 240, generally produces severe palpitation, substernal discomfort and great anxiety. It is the commonest and least serious type of paroxysmal heart action and is often present in otherwise normal hearts. In other subjects, paroxysmal auricular tachycardia appearing in the later years may be the first indication of disease of the coronary arteries. Campbell and Elliott,<sup>34</sup> in a recent study of 100 unselected cases, report 3 patients who have lived fifty years after the onset of their paroxysms, another 18 for more than twenty years, and another 26, making 47 per cent, for more than ten years. Although approximately half the attacks are abruptly terminated by pressure over the carotid sinus, in others the paroxysm may persist and lead after many hours or days, if untreated, to congestive failure or cardiac pain. The treatment of this condition has been outlined in a previous report.<sup>35</sup>

### *Paroxysmal Auricular Fibrillation*

Paroxysmal auricular fibrillation may occur in an otherwise normal heart as a manifestation of thyrotoxicosis, as well as in some persons without any disease. In the absence of demonstrable heart disease, particularly in older subjects, the possibility of a pathologic basis for the disorder must be considered. The report of observations by Willius and Dry<sup>36</sup> on 70 patients with auricular fibrillation but without demonstrable heart disease by clinical, radiographic or electrocardiographic studies indicates benignity of auricular fibrillation under such circumstances, and is in accord with the earlier observations of Orgain, Wolff and White.<sup>37</sup> The latter concluded that paroxysms of auricular fibrillation or of auricular flutter are in some persons merely exaggerated functional disorders of the heart, no more indicative of cardiac disease or of a poor prognosis than premature beats or paroxysmal auricular tachycardia.

### *Paroxysmal Bundle-Branch Block*

Electrocardiographic evidence of bundle-branch block generally signifies organic heart disease and, when present in high degree, must be regarded as indicative of serious heart disease. It is therefore essential to recall that bundle-branch block may occasionally be found as part of the Wolff-Parkinson-White syndrome in young or even older healthy persons. This syndrome is characterized by three important features: a short PR interval of

fully studied group of 100 proved cases.<sup>42</sup> Conversely, slight changes in electrocardiographic tracings occur in a significant proportion of persons of this age group in the absence of angina pectoris.<sup>44</sup>

## CASE 27461

## PRESENTATION OF CASE

A fifty-one-year-old Greek bootblack entered the hospital complaining of pain in the right hip.

One year before admission, the patient developed a dull ache in the right hip; it was noticeable only when he was standing. He attributed the pain to a right inguinal hernia, for which he had been wearing a truss. Six months passed, and the patient's discomfort reached a point where he was forced to stop working. He walked with a limp, and the pain radiated from the iliac crest down the outer aspect of his leg. It was greatly aggravated by weight bearing and relieved almost instantly by lying down. Because his physician suspected a focus of infection, all the patient's teeth were extracted; but the pain continued, and three weeks before admission it was no longer relieved by lying down. At this time, he noticed a weakness in his right leg, which often became tired and numb. In addition, he developed urinary frequency and nocturia (once a night). He had lost 10 pounds in the preceding six months.

The past and family histories were irrelevant.

On examination, the patient was well developed and nourished and in no apparent distress. He was edentulous. The heart was slightly enlarged, and there was a soft systolic murmur at the base. Examination of the lungs was negative. There was a slight fullness of the right side of the abdomen, and a right indirect inguinal hernia. Moderate tenderness and fullness were present in the right sacroiliac region. Examination of the nervous system was negative except that the left knee jerk was slightly more active than the right. Rectal examination was negative.

The temperature, pulse and respirations were normal; the blood pressure was 132 systolic, 80 diastolic.

Examination of the urine was negative, and no Bence-Jones protein could be demonstrated. A phenolsulfonephthalein test was normal. Examination of the blood showed a red-cell count of 5,700,000 with a hemoglobin of 102 per cent, and a white-cell count of 7600. The corrected sedimentation rate was 13 mm., and the hematocrit reading 50 per cent. The nonprotein nitrogen of

the blood serum was 31 mg., the serum proteins 6.4 gm., the calcium 13.5 mg., and the phosphorus 2.58 mg. per 100 cc.; the phosphatase was 5.5 Bodansky units. A blood Hinton reaction was negative. Examination of the stools was negative.

X-ray study of the pelvis showed a large multilobular defect involving the medial half of the right ilium. The outline of the defect was irregular but well defined, and the cortex was destroyed in several places. A questionable soft-tissue mass was visible in the region of the ischial spine. Multiple septums were visible within the area of destruction. Films of the extremities and chest were negative. An x-ray film of the skull showed two rounded areas of decalcification that were considered to be venous lakes. A chest plate was negative. An intravenous pyelogram showed prompt excretion on both sides. The kidney pelves were not completely visible because of overlying gas. There was no definite evidence of renal disease.

On the eleventh hospital day, an exploration of the neck for a parathyroid tumor was performed. The left lower and both upper parathyroid glands were found and appeared normal. The right lower gland could not be identified.

## DIFFERENTIAL DIAGNOSIS

DR. JOSEPH C. AUB\*: The blood calcium was at a high level; the blood phosphorus was low. This x-ray film of the pelvis gives a different impression from what I expected from reading the report. The periosteum of the ilium shows a complete break. It looks to me as if there were a large tumor there, and the rest of the bones look quite normal. Is there a film of the hand?

DR. AUBREY O. HAMPTON: No.

DR. AUB: This picture will influence me considerably, for hyperparathyroid lesions of bones do not cause destruction of the periosteum, and malignant tumors, of course, are associated with such destruction.

DR. HAMPTON: In this pyelogram, I cannot see anything in the kidneys. The kidney outlines and pelves are normal. I am not imagining all this, in spite of the fact that the films are poor. I think you can see that the kidneys are fairly normal.

DR. AUB: Here is a man who had a tumor mass in his pelvis, with no other abnormality on x-ray study. The bones look quite well; there is no evidence of the characteristic osteoporosis of the hyperparathyroid state. The blood calcium was

\*Physician-in-chief, Collis P. Huntington Memorial Hospital, Boston; associate professor of medicine, Harvard Medical School.

high, the blood phosphorus low, and the total protein normal; no Bence-Jones bodies were found in the urine. I am surprised at the tumor mass. I do not like this lesion. It does not look like one due to hyperparathyroid disease, but I probably should have advised operation just as others did.

Then the question arises whether this patient had a parathyroid tumor deep in the chest. The lower parathyroid glands may go down in the chest along with the thymus; I assume that at operation the upper part of the chest was explored.

I see that Dr. Albright wants to say something. Do you want to help me, Dr. Albright?

DR. FULLER ALBRIGHT: No; I want to hinder you. I see that Dr. Hampton is putting up more films. I do not want him to show you too much.

DR. AUB: All right. I assume that the chest was explored, but one cannot always find parathyroid tumors situated down in the chest simply by exploration from a neck incision: one has to open the chest to explore properly.

The reason one would be so anxious to find a parathyroid tumor in this patient is not that the blood calcium was high, but that the blood phosphorus was low. Most patients with osteoclastic tumors have a normal blood phosphorus, although they may have a high blood calcium—as high as 15 or 16 mg. per 100 cc.

What is the differential diagnosis? It is obviously hyperparathyroidism, multiple myeloma, hypernephroma or a carcinoma of the breast, which is very rare in men. The diagnosis of prostatic tumor is much less likely because the metastases of this tumor are not osteoclastic. I rule out myeloma because the high blood calcium in multiple myeloma is practically always associated with high total protein in the blood stream, which was not found in this patient. I rule out breast tumor because it is not reported in the record. I rule out prostatic tumor simply because it does not look like it. Might I ask if exploration of the upper mediastinum was done?

DR. ALBRIGHT: It was done from above. They went down as far as they could but did not feel anything.

DR. AUB: When I first read the report, my diagnosis was hyperparathyroidism, with tumor in the mediastinum, and my second choice was hypernephroma, in spite of the negative urine and in spite of the x-ray examinations that were reported negative. Now that I see the x-ray films,

I really think the kidney shadows do not stand out well.

DR. HAMPTON: Here are two more films taken at the same time. They are not much better. They have the same general appearance.

DR. AUB: Do they satisfy you?

DR. HAMPTON: No; they are unsatisfactory. I think you are correct in saying that the examination was poor.

DR. AUB: The x-ray appearance of the pelvis looks as though it were due to a malignant tumor, whereas the chemical analyses are proper for hyperparathyroidism. Then there is the problem of the soft-tissue mass and also of the weakness in the leg, which implies peripheral-nerve involvement. Largely on the basis of the x-ray films, I am going to make a diagnosis of malignant tumor and not of parathyroid tumor situated in the mediastinum. I did not plan to make that diagnosis when I came here. If I were in charge of the case, what I should propose doing next would be to take a biopsy of the tumor in the bone, before recommending the second operation of cutting the sternum and looking in the upper mediastinum. The most likely diagnosis of the malignant tumor would be a hypernephroma in spite of the normal urine, because it is the most probable malignant osteoclastic tumor.

DR. HAMPTON: This kidney pelvis does appear to have a defect in the superior margin.

DR. ALBRIGHT: We were influenced by another case we had seen before, which I thought was a dead ringer for the case under discussion. That patient had also had pain in the hip, and the roentgenogram demonstrated a lesion in the ilium very similar to the one in this case. Dr. J. H. Means was asked to see the other patient in consultation, and he considered diagnoses of multiple myeloma and hyperparathyroidism, and ordered serum calcium and phosphorus determinations, as well as a search for Bence-Jones protein in the urine. The serum calcium was high, 13 mg., and the serum phosphorus low, 2.0 mg.; small amounts of what was thought to be Bence-Jones protein were found. Accordingly, the consultation was not much help. Some of us thought that the patient had hyperparathyroidism; others considered multiple myeloma. We decided to biopsy the lesion; both sides were apparently wrong. He had an enchondroma, which was removed. The Bence-Jones proteinuria disappeared, but the hypercalcemia persisted. At a somewhat later date, the parathyroid glands were explored, and the

diagnosis of hyperparathyroidism was substantiated.

DR. HAMPTON: I should like to disagree with Dr. Albright. The two cases are not entirely similar. The cortex of the bone is destroyed in the present case, and intact in the other.

DR. ALBRIGHT: Why could not a benign tumor destroy the cortex?

DR. HAMPTON: It expands but does not destroy it, because bone destruction is due to vascular pulsation rather than to tumor invasion.

DR. TRACY B. MALLORY: The next step was what Dr. Aub said that he would advise—a biopsy of the tumor of the ilium. That was done and showed obvious hypernephroma. At that stage, they began to have doubts about the intravenous pyelogram, and a retrograde film was taken, which Dr. Hampton will now show us.

DR. HAMPTON: I might point out that this is the third case within a month in which a serious error has been made by relying on the intravenous pyelogram when a retrograde pyelogram would have told the story. The retrograde pyelogram shows a definite filling defect in the upper calyces. I think it is true, however, that the kidney presented a normal outline on its lateral surface. If we had taken a lateral view and demonstrated the kidney, we should have seen the mass in front of or behind the kidney. This case misled us because a hypernephroma ordinarily presents on the lateral margin.

DR. ALBRIGHT: Why a person should have a high serum calcium and a low serum phosphorus when the cause of the disturbance is a tumor destroying bone is an interesting theoretical question. We treated this case by radiation of the tumor masses; the serum calcium went down to normal, and the serum phosphorus went up to normal. Gradually, both values became abnormal again. I suspected that the tumor might be producing parathyroid hormone. I therefore had it assayed by Dr. J. B. Collip, but no hormone was found.

#### CLINICAL DIAGNOSIS

Hypernephroma, with metastases to right ilium

#### DR. AUB'S DIAGNOSIS

Hypernephroma, with metastases to bone

#### ANATOMICAL DIAGNOSES

Hypernephroma of right kidney, with metastases to right ilium, fifth lumbar vertebra, sacrum and left ilium.

Bronchopneumonia.

Arteriosclerosis, coronary, slight.

Emaciation

Decubitus ulcer.

Operative scar: parathyroid exploration

#### PATHOLOGICAL DISCUSSION

DR. TRACY B. MALLORY: This patient survived nearly three years, and finally died and came to autopsy. He was found to have a still fairly small hypernephroma of the right kidney but a large tumor involving most of the right side of the pelvis. The fifth lumbar vertebra, the sacroiliac joint, a good deal of the sacrum, and the symphysis pubis had all been destroyed by direct invasion.

DR. AUB: Were there any other metastases to the bones?

DR. MALLORY: Neither grossly nor microscopically. A good deal of the bone marrow was aplastic, almost certainly as the result of x-radiation, although there were foci of moderate hyperplasia.

DR. OLIVER COPE: What was the cause of death—intercurrent infection?

DR. ALBRIGHT: The patient got weaker and weaker, and died.

A PHYSICIAN: Did they find the other parathyroid gland?

DR. MALLORY: At autopsy, yes. It was not neoplastic.

DR. AUB: It was normal?

DR. MALLORY: Yes.

#### CASE 27462

#### PRESENTATION OF CASE

A seventy six-year-old man was admitted to the hospital because of severe abdominal pain of four to five hours' duration.

Eight months before entry, he had a brief bout of abdominal cramps lasting about ten minutes. Three weeks before admission, he experienced a similar episode, which responded well to a little whiskey. The patient stated that he began to have pain in the umbilical region two days before coming to the hospital. His relatives, however, who seemed to have watched him closely, were sure that he had been quite well until early on the morning of admission. At this time, he was found groaning from severe abdominal pain, which centered about his umbilicus. A local physician thought that the patient had a perforated ulcer, gave him morphine, and sent him to the hospital.

The patient had practically always enjoyed good health. His weight had been constant for some

time, his appetite was good, and his bowels had been regular, with no recent change in habits or in the character of the stools. Twenty-five years before entry, he had "stomach ulcers," which disappeared within several weeks after treatment of unknown variety. One of his daughters had died of "pelvic cancer."

On examination, the patient was an elderly, slender man with dry, pale skin; he was groaning from pain. His abdomen was convex, tympanitic and tense, with considerable voluntary spasm. There was marked tenderness, most pronounced in the periumbilical region and right lower quadrant. No masses or hernias were present. The heart and lungs were not remarkable. The right eye was blind because of a cataract.

The temperature was 102.4°F., the pulse 104, and the respirations 34. The blood pressure was 130 systolic, 75 diastolic.

Examination of the blood showed a red-cell count of 4,200,000, and a white-cell count of 12,500 with 5 per cent mature polymorphonuclears and 80 per cent immature polymorphonuclears.

A flat roentgenogram of the abdomen showed a large quantity of air beneath both sides of the diaphragm. No dilated loops of small bowel were visible.

Aspiration of the abdomen gave thin, slightly milky fluid. Culture of this fluid grew colon bacilli and hemolytic streptococci.

Exploratory laparotomy was performed under local anesthesia on the morning of entry.

#### DIFFERENTIAL DIAGNOSIS

DR. HENRY FAXON: Does the x-ray film add anything?

DR. JAMES R. LINGLEY: No; it just shows the air beneath the diaphragm, as described.

DR. FAXON: Does it show dilatation of the large bowel?

DR. LINGLEY: No.

DR. FAXON: Any of the small bowel?

DR. LINGLEY: No.

DR. FAXON: The salient features of this case are that the patient was an elderly man, apparently in previous good health, who suddenly developed an acute condition of the abdomen, with a large amount of free gas beneath both diaphragms. He obviously had a peritonitis, and the most arresting single finding was the presence of this gas.

Such collections of subphrenic gas may arise from three main sources. The first is the introduction of air by perforation of the abdominal

wall or diaphragm by trauma or surgery. The history in this case makes it certain that air was not introduced into the peritoneal cavity from without.

The second cause of gas beneath the diaphragm is peritoneal infection with gas-forming organisms. However, if it had been infection in the peritoneal cavity, with the secondary formation of gas, one would expect a longer story and localization of the process beneath the diaphragm on but one side.

The third cause of such gas is the perforation of a hollow viscus, which seems the most likely explanation in this case. Such a perforation could come about in one of two ways—secondary either to an obstruction of such severity that the bowel ruptured or to erosion through a localized ulcerative area. If it were due primarily to obstruction, it would certainly seem that this patient should have had a longer story. The episodes of abdominal cramps referred to in the history eight months and again three weeks before seem to me of too short duration to have any real significance on this basis. I can hardly believe that they represented temporary obstruction that straightened out, although conceivably they might have been due to a volvulus of the colon. Such a condition is common in men and in elderly people, and might have gone on to the point of actually causing perforation in the attack that brought the patient to the hospital, but that seems extremely unlikely.

The perforation of the hollow viscus must have been due to erosion of some actual lesion through the wall of the gastrointestinal tract. Of such lesions, one possibility would be cancer, but it seems to me that with cancer of the rectum or sigmoid the patient would have had either some change in bowel habit or blood in his stools, during the recent past. Had he had a malignant lesion of the right colon, he might well have had very few symptoms, but it would be extremely rare for such a lesion to go on to the point of perforation with a red-cell count of 4,200,000. Lymphoma is another possibility, for the fluid they aspirated from the abdominal cavity was milky and much more consistent with such a diagnosis than with perforation of the colon.

The pain was chiefly periumbilical and in the right lower quadrant, which suggests that this was referred from the region of the terminal ileum, appendix or cecum. The patient might have had acute appendicitis, with an abscess that ruptured, for we know that in elderly patients the story is often atypical. The reference of pain would have been quite in keeping with this diagnosis, and

the fact that no mass was felt means but little, for the abdomen was apparently so tender and distended that I doubt if a mass could have been made out at the time of entry. However, I have never heard of a rupture of an appendix that caused the escape of so much free gas in the peritoneal cavity that could be demonstrated beneath both diaphragms.

Diverticulitis is another lesion of the bowel that could perforate; it is not usually associated with bleeding by rectum or anemia, does not give rise to many antecedent symptoms, and can perforate with the escape of gas in the peritoneal cavity. However, the signs and symptoms of diverticulitis are characteristically in the left lower quadrant, whereas it seems to me that in this case the localization of the pain was too much on the right side to make diverticulitis seem likely.

The doctor who referred the patient here sent him in with a diagnosis of perforated ulcer, which, despite certain definite objections, seems to me the most likely diagnosis. A perforated ulcer is one of the few lesions that give rise to the escape of such a large amount of gas. Such a lesion might well cause gas beneath both diaphragms, furthermore, with the obliquity of the attachment of the mesentery, the gastric fluid as it gravitated downward would give rise to pain more on the right than on the left side. The ulcer story of the past is so vague that it means but little. I am distinctly surprised that colon bacilli were cultured when the perforation was only four or five hours old. My final diagnosis is peritonitis due to dissemination of intestinal contents from erosion through the gastrointestinal tract, most probably perforation of a peptic ulcer.

DR ROBERT LINTON: Did Dr Faxon include carcinoma as a possibility?

DR FAXON: Carcinoma of the stomach is certainly a good possibility, but if the lesions had been malignant, the patient would probably not have been in such good health up to the time of entry.

DR ALLEN G. BRAILEY. What about ulcer of a Meckel's diverticulum?

DR FAXON. I think it would be extremely unlikely for a patient to show the first symptoms and suffer a perforation of a Meckel's diverticulum at the advanced age of seventy-six. Periumbilical pain would be quite in keeping with a Meckel's diverticulum that had gone on to the point of perforation, but I should not have expected the gas seen under the diaphragm to have occurred unless in the x-ray plate there were signs of small-

bowel obstruction behind the Meckel's diverticulum.

DR ARTHUR W ALLEN: Are you not worried about the story of periumbilical pain of two days' duration?

DR FAXON: I am very much worried about it. When I first read over this case, I thought the patient certainly had a perforated ulcer, but the more I studied it the more I worried over the atypical localization of the pain.

DR ALLEN: I think they should tell you whether the fluid had an odor to it.

DR FAXON: I hoped that they might.

DR TRACY B. MALLORY: Dr Ulfelder, will you tell us about that?

DR HOWARD ULFELDER: Our differential diagnosis ran much like Dr Faxon's but we never seriously entertained a diagnosis other than that of perforated ulcer. His condition was good preoperatively. We operated under local anesthesia through a right upper-quadrant paramedian incision. On opening the abdomen, we found free, nonodorous milky fluid that seemed to come from the right gutter. Exploration of the duodenum and stomach anteriorly revealed no evidence of perforation or disease. We opened the mesocolon below the stomach and explored the lesser cavity, the posterior aspect of the stomach and the duodenum, and still found no cause for the disease. We then turned our attention to the right gutter and, in tracing down into the pelvis, were suddenly greeted with a gush of foul-smelling, thin fluid. His condition became much worse. We believed that the patient had a perforation of the large bowel, of unknown cause. No further surgery was attempted, since the blood pressure dropped so low that it could not be measured. The wound was closed without drainage, and the patient was sent back to the ward for a futile attempt at conservative therapy.

#### CLINICAL DIAGNOSIS

Perforated peptic ulcer

#### DR FAXON'S DIAGNOSES

Perforated peptic ulcer

General peritonitis

#### ANATOMICAL DIAGNOSES

Carcinoma of sigmoid, with perforation

Diverticulosis of sigmoid

Peritoneal abscess, pelvic

Peritonitis, acute, generalized

Pneumoperitoneum

Laparotomy

Prostatic hyperplasia

## PATHOLOGICAL DISCUSSION

DR. MALLORY: At autopsy, we found in the large bowel a number of diverticula. At first, we were suspicious that one of these had ruptured, but they all seemed intact. Finally, just at the rectosigmoid junction, we found a carcinoma with a deeply penetrating central ulceration that had perforated into the abdominal cavity just above the pelvic floor. There an abscess had formed and had evidently been present for some

time, since there was dense fibrinopurulent exudate over all the viscera in this area. In the upper abdomen, there was a generalized milder and evidently more recent peritonitis. I should think that the perforation of the carcinoma and the formation of the pelvic abscess preceded entry to the hospital by a number of days, and that the acute symptoms probably represented a rupture of that abscess into the general peritoneal cavity. Why the pain was periumbilical, I cannot say.

## APPROVING AUTHORITY

THE attention of the members of the Massachusetts Medical Society is directed to a letter and enclosures that have been received by the Secretary from Dr. Stephen Rushmore, chairman of the Massachusetts Approving Authority for Colleges and Medical Schools. This correspondence should make for a better understanding of a matter that provoked considerable discussion at the October 1 meeting of the Council.

Much dissatisfaction, of late years, has been expressed with the Massachusetts Medical Practice Act. It has been described as archaic and most certainly not in keeping with the advances in the science of medicine. As the result of this dissatisfaction, the act was amended in 1936 to create an approving authority in whose hands would be

the power to set up minimum standards for colleges and medical schools that must be met if the graduates of these colleges and medical schools were to be permitted to take the examinations offered by the Massachusetts Board of Registration in Medicine. The amended law provided that the initiative in seeking the approval of this authority must come from the school whose graduates wish to be licensed in Massachusetts.

In the same session of the Legislature, this act was further amended on the advice of Governor Curley. When the bill was presented to the Governor for his approval, he said that he was very much in favor of the thought behind it. He believed, however, that because the decisions of the Approving Authority might involve the property rights of certain individuals,—owners of schools and students whose education represented property rights,—the bill should provide for a review of certain of the decisions of the Approving Authority by a judge of the Superior Court. He added that the property rights of the individual are guaranteed by the Constitution and that the open recognition of this principle in the bill would add strength to the bill itself.

The bill went back to the Legislature and was amended to incorporate this suggestion of the Governor. While it was taking this second trip through the Legislature, it was still further amended to postpone the date of its operation until 1939. The proponents of the bill accepted this latter amendment because it was pointed out that if this bill became effective immediately, certain schools and certain individuals who had matriculated in those schools in good faith might be seriously affected. The thought that some schools should be afforded reasonable time to improve their standards had considerable appeal to the legislators.

The law was again amended in 1938 to extend further its date of operation. The language of this latter amendment is contained in Chapter 247, Acts of 1936, Section 3, as amended. Dr. Rushmore's letter quotes this section. It is particularly referred to here because it does seem to clarify a matter that was discussed at length at

the October 1 meeting of the Council, when the President and Secretary were directed "to give their attention to this matter with a view of enlightening the Council as to what the situation is."

The situation may be briefly stated as follows: an approving authority for colleges and medical schools is now functioning in Massachusetts. This authority has already inspected all medical schools in Massachusetts that have requested inspection and has approved three of these. The initiative for such an inspection must come from the college or medical school. Certain decisions of the Approving Authority are subject to a review by a judge of the Superior Court, sitting in Suffolk County.

Applicants who matriculated in a medical school previous to January 1, 1941, cannot be barred from taking the examination for licensure in Massachusetts even though the school from which they graduated has not been endorsed by the Approving Authority at the time of graduation.

## THE SCHOOL-LUNCH PROBLEM IN BOSTON

IN the September 18 issue of the *Journal*, an editorial commented on the nutritional deficiencies commonly found in American diets and on the consequent importance of the school lunch for children. Since then, a report by the Advisory Committee on School Hygiene,\* dated April, 1940, and dealing with the school-lunch problem as it exists in Boston, has been received. The recommendations in the report are so significant that they are quoted in full:

(1) The situation regarding school lunches for pupils in the public schools of Boston presents problems worthy of careful and prompt consideration by the School Committee.

(2) A thorough reorganization of the system of providing lunches for the pupils is urgently needed.

(3) To accomplish this result, responsibility for the management of the cafeterias in all the public schools of Boston should be placed in the hands of a single director.

(4) Besides the fundamental requirement of high character and organizing ability, the director should have excellent training in and a thorough knowledge of nutrition, as well as training and experience in lunchroom management and the preparation of attractive, palatable food. The appointment of such an individual will require careful consideration. The professional qualifications required for work of this kind have been studied by the American Dietetic Association and the American Home Economics Association.

(5) The functions of the proposed director should include the purchase of food and the supervision of menus, as well as the management of the cafeterias. The qualifications for lunchroom managers should be carefully drawn up, so that efficient workers may be obtained.

(6) The director should endeavor to exemplify in the lunchrooms the dietetic and hygienic principles taught in the schools.

(7) The sale of undesirable foods, such as candy and tonic, in the cafeterias or on the school premises should be stopped. The school children should not be allowed to leave the school premises during the lunch hour, and sales of candy or food to them by outside persons should be discouraged as far as possible.

(8) In some, if not in all the schools, more time should be allowed for lunch.

(9) In some of the schools, the lunch program will require improved cafeteria facilities, more equipment, and better hand-washing facilities and more soap and towels.

(10) Adequate reorganization demands replacement of unqualified cafeteria managers by suitably trained personnel. These should have faculty standing in order that they may be in a position to confer with the school administrators, teaching staff and school health group on common problems of nutrition education.

(11) The director should exercise authority not only over all the cafeterias in the schools, in so far as they serve the children, but also over the following additional activities: food service to nutrition classes; distribution of milk and other foods; and lunches served to teachers or others, if any.

These recommendations received favorable action by the School Committee, and money was recently appropriated to pay the salary of such a director. The Civil Service Commission, in accordance with law, has circulated a notice of an examination to be taken, on November 22, by applicants for the position of "Supervisor of School Lunches."

\*This committee is an official body appointed by the School Committee of Boston. The report was presented to the School Committee after having been approved by the Director of School Hygiene.

As stated in the notice, the duties of the supervisor are as follows

To draw up specifications for the purchase of food supplies, to standardize recipes for the school lunch rooms, to plan menus based upon adequate nutrition standards, to have supervision of all menus, of the direction and preparation of school lunches, of the distribution of milk and other supplies and of lunch room sanitation, to analyze equipment on hand in the lunchrooms and recommend redistribution to develop nutrition education through correction with the health education program, and to perform related work as required

A knowledge of cost accounting is necessary

Applicants must have executive ability adequate to meet organization requirements for the establishment of a city wide lunch system, and ability to work with and to direct the work of others

This new office will be a position of prime importance for the health of Boston's school children. All persons interested in their welfare will recognize that the children should receive school lunches, at minimum cost, that compare favorably with those provided by other forward looking communities

Unfortunately, certain conditions raise a question concerning the adequacy of the provisions for obtaining a properly qualified person. Firstly, regulations require that applicants be citizens domiciled in the State at least a year and in Boston at least six months. Since a school lunch system of this scope is nonexistent in Massachusetts, this provision limits the examinees to persons having comparatively little experience. Secondly, the General Laws provide for veterans preference among applicants passing with grades above 70 per cent. Thirdly, the salary is less than those paid to the holders of similar positions in cities smaller than Boston. And, finally, there is no limitation concerning age. It is hoped that the written examination will be so inclusive and the physical examination so thorough that they can be passed only by persons who are adequately trained and physically fitted to perform the important and arduous duties of the new office.

## MEDICAL EPONYM

### LANDRY'S PARALYSIS

Dr Jean Baptiste Octave Landry (1826-1865) published "Note sur la paralysie ascendante aigue [Note on Acute Ascending Paralysis]" in the *Gazette hebdomadaire de medecine et de chirurgie* (Paris) (6: 472-474 and 486-488, 1859). A portion of the translation follows

The object of this note is to call attention to a morbid condition that is rather uncommon and generally unknown but deserves a place among the most remarkable diseases in the pathological category

In these cases, the symptoms, beginning in the extremities, successively involve the upper portions of the body, those more central relatively to the nervous system becoming gradually augmented in intensity in the invaded organs. These symptoms frequently tend to become general, and then produce a definite *general paralysis* with all the characteristics of that of the insane

I simply add that, nearly always slowly progressive, it occasionally runs a very rapid course, and may become serious or even fatal in a very short time. It is this variety that I propose to designate *ascending* or *acute centripetal paralysis*

## MASSACHUSETTS MEDICAL SOCIETY

### APPROVING AUTHORITY

The following letter and enclosures were recently received from Dr Stephen Rushmore, chairman of the Approving Authority for Colleges and Medical Schools, and are reprinted for the information of the members of the Massachusetts Medical Society

MICHAEL A. TIGHE, *Secretary*

\* \* \*

Dear Dr Tighe

In reply to your letter of inquiry on the part of the Massachusetts Medical Society as to the work of the Approving Authority for Colleges and Medical Schools, I regret that the nature of our work precludes the giving out of full details since so much of the information which comes to us may properly be regarded as confidential.

I may say, however, that, under the statute, the inactive rests with the institution seeking approval, and that the Approving Authority has inspected all the medical schools in Massachusetts that have requested inspection. Following inspection, the Approving Authority has approved the medical schools of Boston University, Harvard University and Tufts College.

Attention should be called to the fact that no applicant for examination for registration as a physician may be

rejected by the Board of Registration in Medicine as a graduate of a nonapproved school until 1945. Chapter 247, Acts of 1936, Section 3 (as amended), reads as follows:

The provisions of said section two of said chapter one hundred and twelve as existing immediately prior to January first, nineteen hundred and forty-one, shall continue to govern as to the eligibility of any applicant for registration as a qualified physician who shall have matriculated prior to said date in any legally chartered medical school having power to confer degrees in medicine, but subject, however, to the provisions of section two of chapter one hundred and seventy-one of the acts of nineteen hundred and thirty-three.

Attention should be called also to the fact that the statute specifies that one of the conditions of eligibility for examination by the Board of Registration in Medicine is that the candidate "has received the degree of Doctor of Medicine . . . from a legally chartered medical school . . . approved by the Approving Authority. . . ." Presumably, this means approved by the Approving Authority at the time when the degree was conferred.

I enclose a copy of the "Requirements for Approval of Colleges, Universities and Medical Schools," published in 1936 by the direction of the statute, and a copy of Section 2, Chapter 112, of the General Laws as most recently amended.

The statute of 1936, as amended in 1938, thus gave medical schools nearly five years in which to meet the requirements published in 1936 before inspection with effective approval or nonapproval could occur.

STEPHEN RUSHMORE, M.D., *Chairman*

State House  
Boston

#### REQUIREMENTS FOR APPROVAL OF COLLEGES, UNIVERSITIES AND MEDICAL SCHOOLS

##### *Qualifications Required for Approval of a College or University as Giving Two Years of Premedical Collegiate Work, including Physics, Chemistry and Biology*

The institution will be approved if it has already been approved by the Association of American Universities or the Regional Association of Colleges and Secondary Schools in the territory in which the institution is located.

Since approval by the above-noted organizations may be lacking because it has not been sought or has been refused, and since an educational institution should be judged by its objectives and its adequacy in attaining these objectives, specific requirements may present considerable variation. The following general requirements have, however, been established:

(1) The curriculum should presuppose educational qualifications required for graduation from a public high school as a condition for entrance to the institution.

(2) The instruction should be at the collegiate level generally required of institutions giving similar curricula in the regional group.

(3) Since the teacher is the heart of an educational institution, the competence of the faculty, the organization of the faculty, the working conditions for the faculty and the quality of the instruction will receive special attention.

(4) The physical facilities, including library, must be adequate for the objectives of the institution.

(5) The administrative organization and personnel should be adequate for accomplishing the objectives of the institution.

(6) The institution should provide evidence of financial resources adequate for and effectively applied to the support of its educational program.

##### *Qualifications Required for Approval of a Medical School*

The minimum requirements for an approved medical school as set by the statute and by ruling of the Approving Authority under the statute are as follows:

(1) The school must be legally chartered.

(2) If the school confers degrees in medicine, the school must be legally empowered to confer degrees in medicine.

(3) If the school confers degrees in medicine, the school must see to it that the statutory conditions are fulfilled, namely, that the candidate shall have taken a course of at least four years of not less than thirty-two weeks in each year before the degree is conferred.

(4) If the power of the school to confer degrees is restricted under the charter, the degrees conferred must be under the restriction of the charter.

(5) The school must restrict admission of candidates to those who have had at least two years of premedical work in an approved college, including courses in physics, chemistry and biology.

(6) A candidate seeking admission to an approved school, after attendance in a nonapproved school, must receive specific approval from the Authority both as to admission and status after admission.

(7) A candidate admitted to advanced standing must spend at least one year in the school, completing the regular fourth or last-year course of study, if the four-year course is given, or the year next preceding the year of internship, if internship is required for graduation, before the degree is conferred. Before admission to such fourth year, the candidate seeking admission to advanced standing must fulfill all the conditions required of candidates for admission to the fourth year who have taken the uninterrupted course.

(8) The administration of the school must be under the supervision and control of a dean or other administrative officer who is familiar with contemporary medical education, its standards and procedures and who has authority adequate for the proper performance of his duties.

(9) The school must provide adequate preclinical courses in anatomy (including histology and embryology), physiology (including biochemistry and pharmacology) and pathology (including bacteriology and immunology). Average courses for these groups are approximately as follows: anatomy group 15 per cent of the whole medical course; physiology group 15 per cent; pathology group 15 per cent. The whole medical course should cover approximately four thousand (4000) hours.

(10) For the preclinical courses there should be no less than nine full-time teachers of professional rank: for anatomy group, three; physiology group, three; pathology group, three. There must be adequate full-time or part-time assistants, and technicians. This estimate is on the basis of fifty students in each class.

(11) In order that a teacher may be regarded as ade-

quate for a full time professorship (professor, associate professor, assistant professor) he must (1) have had adequate opportunity to become familiar with his subject (2) have had adequate experience as a teacher of his subject, and (3) have attained such a position in his profession that he is recognized by his fellow workers in his specialty as competent

(12) The laboratories for each preclinical subject must be adequate with ample desk room for work, and locker room for supplies and equipment

(13) Each department must have equipment adequate for its needs, for demonstration purposes as well as for routine work with students, for research by members of the faculty, and there must be a sufficient number of rooms for meetings of whole classes for lectures or demonstrations with accessory apparatus for these purposes

(14) There must be an adequate working library for the school, with books of reference and magazine files and tables or desks for work, under the charge of a competent librarian

(15) There must be adequate clinical material available for teaching purposes, for all branches of medicine with especial emphasis on medicine, surgery and obstetrics

(16) The records of the school must be adequate to show the actual condition of the school, and the status of each student, including his premedical record

(17) The financial statement of the school must be so presented as to show whether the school is or is not actually conducted in accordance with its charter as a noncommercial institution

#### QUALIFICATIONS AND EXAMINATION OF APPLICANTS FOR REGISTRATION AS QUALIFIED PHYSICIANS

Amendment of Section 2, Chapter 112, of the General Laws (Acts of 1939, Chapter 451, Section 37), approved August 10, 1939

**Section 2** Applications for registration as qualified physicians, signed and sworn to by the applicants shall be made upon blanks furnished by the board of registration in medicine, herein and in section three to twenty-three, inclusive, called the board. Each applicant who shall furnish the board with satisfactory proof that he is twenty-one or over and of good moral character, that he possesses the educational qualifications required for graduation from a public high school, that he has completed two years of premedical collegiate work, including physics, chemistry and biology, in a college or university approved by a body consisting of the secretary of the board, the commissioner of education and the commissioner of public health, in this section referred to as the approving authority, that he has attended courses of instruction for four years of not less than thirty-two school weeks in each year, or courses which in the opinion of the board are equivalent thereto in one or more legally chartered medical schools, and that he has received the degree of doctor of medicine, or its equivalent, from a legally chartered medical school having the power to confer degrees in medicine and approved by the approving authority, shall, upon payment of twenty-five dollars, be examined, and if found qualified by the board be registered as a qualified physician and entitled to a certificate in testimony thereof, signed by the chairman and secretary. An applicant ag-

grieved by the refusal of the approving authority to approve a medical school under this section shall be entitled to have the reasonableness of such refusal reviewed by a justice of the superior court, whose decision shall be final. An applicant failing to pass an examination satisfactory to the board shall be entitled within one year thereafter to a reexamination at a meeting of the board called for the examination of applicants, upon payment of a further fee of three dollars, but two such reexaminations shall exhaust his privilege under his original application. The board, after due notice, and hearing, may revoke any certificate issued by it to, and cancel the registration of, any physician convicted of a felony, and may, at any time after the expiration of one year thereafter, reissue any certificate so revoked, and register anew any physician whose registration was so canceled. The board, after due notice and hearing, may suspend, for a period not exceeding one year, any certificate issued by it to and cancel the registration of, any physician who has been shown at such hearing to have been guilty of gross and confirmed use of alcohol in any of its forms while engaged in the practice of his profession, or of the use of narcotic drugs in any way other than for therapeutic purposes, or of abuse of the authority granted in section two hundred and nine A of chapter ninety-four or of publishing or causing to be published, or of distributing or causing to be distributed, any literature contrary to section twenty-nine of chapter two hundred and seventy-two or of acting as principal or assistant in the carrying on of the practice of medicine by an unregistered person or by any person convicted of the illegal practice of medicine or by any physician whose registration has been canceled, and whose certificate has been revoked or suspended, by the board, or of aiding and abetting in any attempt to secure registration, either for himself or for another, by fraud, or in connection with his practice, of defrauding or attempting to defraud any person. Except as otherwise provided herein, the board may, at any time, reissue any certificate so revoked and register anew any physician whose registration was canceled.

The approving authority shall, upon the request of any college, university or medical school in this Commonwealth, inspect said college, university or medical school and notify its trustees or other governing body in writing if said college, university or medical school is approved by the approving authority for the purposes of this section, or if not, what steps said college, university or medical school must take in order to gain the approval of the approving authority.

Any college, university or medical school desiring to be approved for the purpose of this section may file with the approving authority a written request for the approval of such college, university or medical school, and thereupon a public hearing shall be seasonably granted by the approving authority and a written decision made by it within twenty days after the termination of such hearing and the applicant for such approval shall be notified of such decision. A written decision of the approving authority refusing to approve any college, university or medical school shall not become effective until thirty days after written notice of such decision is given to the college, university or medical school seeking such approval. Every such college, university or medical school aggrieved by such refusal shall have the right to file a

petition in the superior court for Suffolk County to revise or reverse the decision of the approving authority. Notice of the entry of such petition shall be given to the secretary of the board of registration in medicine and all proceedings connected therewith shall be according to rules regulating the trial of civil causes without juries. The court shall hear the case and finally determine whether or not such approval shall be granted or revised.

Upon the filing of such a petition within the aforesaid period of thirty days, then the said decision of the approving authority shall not become effective until a final decree affirming said decision is entered upon the aforesaid petition.

The board shall examine an applicant who is an alien only if he presents to it a certificate from the court in which he shall have filed his declaration of intention to become a citizen of the United States, or from the Immigration and Naturalization Service of the United States, showing that he has declared his intention to become such a citizen, or a copy of such declaration of intention, certified by the clerk of such court. In case the applicant is subsequently registered, unless he shall present to the board, within five years following the filing of the certificate or certified copy hereinbefore referred to, his completed naturalization papers showing that he is a citizen of the United States his certificate of registration shall be revoked and his registration canceled. The foregoing provisions of this paragraph shall not apply to limited registration under section nine or section nine A or to any alien physician of distinguished merit and ability, duly licensed to practice his profession in any foreign country wherein the requirements for the issuance of such a license are not substantially lower than those of this commonwealth, while he is temporarily teaching in this commonwealth in a medical school approved by the approving authority.

Section 3, Chapter 112, of the General Laws (Acts of 1936, Chapter 247):

*Section 3.* The provisions of said section two of said chapter one hundred and twelve as existing immediately prior to January first, nineteen hundred and forty-one, shall continue to govern as to the eligibility of any applicant for registration as a qualified physician who shall have matriculated prior to said date in any legally chartered medical school having power to confer degrees in medicine, but subject, however, to the provisions of section two of chapter one hundred and seventy-one of the acts of nineteen hundred and thirty-three.

## SECTION OF OBSTETRICS AND GYNECOLOGY\*

### FATAL NEPHRITIS IN PREGNANCY

A thirty-seven-year-old para III had had no prenatal care. When she was approximately twenty-four weeks pregnant, she called a physician because of bleeding. He referred her immediately to the hospital. For two weeks, the patient had

had considerable swelling of the face, abdomen and legs, with blurred vision and epigastric pain.

On examination, the blood pressure was 158 systolic, 100 diastolic. Four hours after entry, the patient delivered herself spontaneously of twins. The kidneys subsequently shut down, and the patient succumbed to uremia a week after admission. Autopsy showed chronic nephritis as the cause of death.

*Comment.* This death cannot be attributed to poor obstetrics; ignorance or indifference on the part of the patient was the real cause of death. Had this patient been seen early in her pregnancy, the diagnosis of chronic nephritis would undoubtedly have been made, and if the condition had not appeared serious enough to warrant abortion, she would have been under constant medical control.

It is commonly believed that any patient with nephritis who is pregnant and shows serious suppression of kidney function as early as five months must have considerable chronic kidney damage. The only way to prevent such deaths is to impress on the laity the value of early prenatal care. If this advice is not generally promulgated and if clinics are not established for all pregnant women, such a disaster as this must recur. Even though the necessity of prenatal care is well recognized and clinics are made available for everyone, no law compels the pregnant woman to accept these advantages, and a few such disasters are bound to occur.

### DEATHS

**BARTLETT**—WALTER O. BARTLETT, M.D., of Boston, died November 5. He was in his sixty-third year.

Born in Natick, Dr. Bartlett received his degree from Harvard Medical School in 1902. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

His mother, a brother and a sister survive him.

**EDGAR**—WILLIAM L. EDGAR, M.D., of Athol, died October 11. He was in his seventieth year.

Dr. Edgar received his degree from the Hahnemann Medical College of Philadelphia. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

**LEACH**—ALBERT C. LEACH, M.D., of Orange, died November 9. He was in his seventy-first year.

Born in Portsmouth, New Hampshire, Dr. Leach received his degree from Dartmouth Medical School in 1894. He was a fellow of the Massachusetts Medical Society and the American Medical Association.

He is survived by his widow, two daughters and two sons.

**LORD**—FREDERICK T. LORD, M.D., of Boston, died November 4. He was in his sixty-seventh year.

\*A series of selected case histories by members of the section will be published weekly. Comments and questions by subscribers are solicited and will be discussed by members of the section. Letters should be addressed to Dr. Raymond S. Titus, Secretary, 330 Dartmouth Street, Boston.

Born in Bangor, Maine, Dr Lord received his degree from Harvard Medical School in 1900. After internship at the Massachusetts General Hospital, he was appointed to the staff in 1903 and was a member of its board of consultation at the time of his death. He was made a member of the faculty of the Harvard Medical School in 1905 and served for many years, being appointed professor of clinical medicine in 1930 and professor emeritus in 1935. He was a former vice president of the National Tuberculosis Association, and at the time of his death was president of the Massachusetts Tuberculosis League. He was a fellow of the Massachusetts Medical Society and the American Medical Association and a member of the Association of American Physicians, the American Society for Clinical Investigation and the American Clinical and Climatological Association.

His daughter and two grandchildren survive him.

## CORRESPONDENCE

### URINARY FINDINGS BEFORE AND AFTER A MARATHON RACE

To the Editor: The accompanying chart of urinalyses, prepared by William T. Wright, chief technician of the

renal excretory reaction to the long sustained effort involved in a twenty-six mile race. Various other observers have made similar reports following athletic contests, and this chart is presented simply as additional corroborative evidence of normal kidney response to strenuous exercise.

Urine specimens were obtained both before and after the 1941 Boston marathon race from twenty participants—a fairly good number, considering the size of the starting list, the fact that some starters drop out, the physical condition of the runners at the finish, and the general confusion prevailing.

Several of the determinations were of little or no significance. Following the race, the color tended to be stronger, and the majority of specimens, which had previously been clear, were cloudy or hazy. All but three were acid before and after the race, and of the three that were very faintly alkaline before the race, two were acid afterward. The specimen from one contestant (No. 11) gave a faintly positive test with phenylhydrazine before the race, and that of another (No. 1) afterward. One (No. 8) showed a trace of acetone before the race, and two others (Nos. 16 and 20) showed 4 mg per 100 cc. and a trace, respectively, afterward.

The chart is self-explanatory. The interesting features,

Alters at onset of (Benedict's test) — faint — green — cloudy — heavy — yellow — hyaline — (sediment) — finely gran.

— granular — low power field

\*Ran only 11 miles

John Hancock Mutual Life Insurance Company medical laboratory, may be of some clinical interest in depicting

of course, are the occurrence, following the race, of an incredible number of casts in most of the urines, as shown

by low-power microscopic field, and the consistent finding of albumin in varying quantities (0.01 to 0.04 per cent of albumin is equivalent to a very faint trace or faint trace as shown by the heat test or the nitric acid ring test). It should be noted that no red blood cells were found. Interesting, too, are the reactions to Benedict's test after the race, some of which might be interpreted as showing considerable sugar, although the actual quantity of fermentable sugar was extremely small in all cases (the fermentable-sugar percentage was determined by comparison of picramic acid colorimetric readings both before and after fermentation of the urine and not by the ordinary saccharometer, which is of questionable accuracy). Only one contestant (No. 2) furnished a subsequent specimen, which was procured four weeks later during a rest period while in training for a twenty-mile race; this urine was entirely normal, both chemically and microscopically.

## MISCELLANY

### RÉSUMÉ OF COMMUNICABLE DISEASES IN MASSACHUSETTS FOR SEPTEMBER, 1941

DISEASES	SEPTEMBER 1941	SEPTEMBER 1940	FIVE-YEAR AVERAGE*
Anterior poliomyelitis	67	14	37
Chicken pox	106	105	83
Diphtheria	10	7	13
Dog bite	1197	955	895
Dysentery, bacillary	110	17	22
German measles	28	18	22
Gonorrhea	403	391	484
Measles	168	211	114
Meningitis, meningococcal	8	—	3
Meningitis, other forms	2	—	—
Mumps	233	125	122
Paratyphoid fever	2	3	10
Pneumonia, lobar	107	135	119
Scarlet fever	246	128	144
Syphilis	361	403	429
Tuberculosis, pulmonary	248	251	235
Tuberculosis, other forms	26	32	26
Typhoid fever	7	5	12
Undulant fever	8	9	4
Whooping cough	546	474	471

\*Based on figures for preceding five years

### GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from: Attleboro, 2; Barnstable, 1; Billerica, 1; Boston, 9; Brockton, 2; Cambridge, 3; Danvers, 1; Fall River, 2; Falmouth, 2; Fitchburg, 1; Hanson, 1; Haverhill, 1; Lakeville, 1; Lynn, 1; Manchester, 1; Medford, 1; Melrose, 2; Merrimac, 1; Middleborough, 1; Natick, 2; New Bedford, 3; Newton, 2; North Attleborough, 2; North Brookfield, 1; Salem, 1; Sharon, 1; Somerville, 2; Southwick, 1; Spencer, 1; Springfield, 2; Sterling, 1; Stoneham, 1; Swansea, 2; Taunton, 1; Wareham, 1; Watertown, 1; Westwood, 1; Wilbraham, 1; Williamstown, 1; Worcester, 5; total, 67.

Diphtheria was reported from: Fall River, 9; Somerville, 1; total, 10.

Dysentery, bacillary, was reported from: Boston, 2; Danvers, 6; Dunstable, 91; Fairhaven, 1; Lowell, 1; Northampton, 1; Watertown, 1; Winchester, 1; Worcester, 6; total, 110.

Infectious encephalitis was reported from: Fall River, 1; Worcester, 1; total, 2.

Meningitis, meningococcal, was reported from: Chico-

pee, 1; Easthampton, 1; Fort Devens, 1; Framingham, 1; Ipswich, 1; Manchester, 1; Quincy, 2; total, 8.

Meningitis, other forms, was reported from: Cambridge, 1; Lowell, 1; total, 2.

Paratyphoid fever was reported from: Boston, 1; Brookline, 1; total, 2.

Pellagra was reported from: Boston, 2; Fall River, 1; total, 3.

Rocky Mountain spotted fever was reported from: Quincy, 1; total, 1.

Septic sore throat was reported from: Fall River, 1; Boston, 1; total, 2.

Tetanus was reported from: Brockton, 1; total, 1.

Trachoma was reported from: Worcester, 1; total, 1.

Trichinosis was reported from: Boston, 4; Fall River, 1; Medford, 2; Middleborough, 1; total, 8.

Typhoid fever was reported from: Chicopee, 2; Fall River, 1; Marblehead, 1; Scituate, 1; Winthrop, 1; Woburn, 1; total, 7.

Undulant fever was reported from: Carver, 1; Leominster, 1; Newburyport, 1; Northampton, 1; Pittsfield, 1; Somerville, 1; Templeton, 1; Webster, 1; total, 8.

Anterior poliomyelitis has increased slowly this season but has not reached epidemic proportions.

Meningococcal meningitis, pulmonary tuberculosis, scarlet fever, undulant fever and whooping cough were above the five-year averages.

Chicken pox, German measles, measles, mumps, scarlet fever and whooping cough, although slightly above the five-year averages, have shown the usual seasonal declines.

Dog bite not only has shown the usual seasonal increase but has reached record high figures for the month.

Bacillary dysentery has shown a steady increase this summer and has reached record high proportions for September.

Diphtheria, gonorrhea, lobar pneumonia, paratyphoid fever, typhoid fever and syphilis were below the five-year averages.

## NOTES

Award of the Louis E. Kirstein Fellowship to Dr. Sidney Cohen, A.B. '33, M.D. '37, assistant in medicine and in bacteriology, was among the grants of \$5925 at the Harvard Medical School for the current academic year recently announced by Harvard University. This fellowship, to promote "scientific medical education," was established through a gift made to Harvard University by eighty-nine friends of Mr. Kirstein in honor of his seventieth birthday and in recognition "of their affection for him as a man and their admiration of him as a humanitarian." Kenneth T. Bird, 4M, of Watertown, was awarded the James C. Melvin Scholarship. National Scholarship renewals were awarded to James S. Clarke, 2M, of La Grange, Illinois; Martin E. Flipse, 2M, of Douglaston, Long Island, New York; Winsor C. Schmidt, 2M, of Rye, New York; Louis E. Ward, 3M, of Mt. Vernon, Illinois; Allan L. Friedlich, Jr., 3M, of New York City; Glen R. Leymaster, 4M, of Aurora, Nebraska; Clarke T. Case, 4M, of Pynmana, Burma; and Laurence G. Wesson, Jr., 4M, of Boston.

Dr. Bennett F. Avery, dean of Boston University School of Medicine, recently announced that the Samuel Gold Award, presented annually to the school's outstanding first-year student by Phi Lambda Kappa fraternity, has been given to Sarkis A. Sarkisian, of Bridgewater.

## NOTICES

## ANNOUNCEMENTS

Dr. RALPH H. HOPKINS announces the removal of his office from the Hotel Westminster, Boston, to 31 Bay State Road

Dr. DAVID W. WELLS announces the removal of his office from the Hotel Westminster, Boston, to 31 Bay State Road

## BOSTON MEDICAL HISTORY CLUB

There will be a meeting of the Boston Medical History Club at the Boston Medical Library, 8 Fenway, on Wednesday, November 19, at 8:15 p.m. Dr. Arturo Castiglioni will speak on Giovanni Battista Morgagni in relation to the evolution of medical thought in the eighteenth century

All interested persons are cordially invited to attend

ROBERT DAWSON EVANS  
MEMORIAL LECTURE

Dr. ALVAH H. GORDON, professor of medicine emeritus at McGill University Faculty of Medicine Montreal, will give the first in the series of Robert Dawson Evans Memorial Lectures on Friday, November 21 at 8:15 p.m. in the Evans Auditorium, 78 East Concord Street, Boston. His subject will be Bone Changes in Certain Medical Diseases.

Physicians and medical students are cordially invited to attend

## BOSTON SOCIETY OF BIOLOGISTS

A meeting of the Boston Society of Biologists will be held at the Harvard Biological Laboratories, Divinity Avenue, Cambridge, on Wednesday, November 19 at 8 p.m.

## PROGRAM

Chronic Gonadotropin and Luteal Secretion in Primates Dr. Frederick L. Hisaw

On Seasonal Changes in the Testes of Deer and Their Relationship to the Growth of Antlers Dr. George B. Wislocki

Biochemical Aspects of Antler Growth Dr. Joseph C. Aub, Miss Regina McLean and Miss Dorothy M. Tibbets

## WALTHAM MEDICAL MEETING

The regular clinicopathological staff conference of the Metropolitan State Hospital will be held at the hospital on Wednesday, November 26, at 8 p.m. Two cases of diabetes will be presented by Drs. Clementine McKeon, Richard C. Wadsworth and Elvin V. Semrad and will be discussed by Dr. Alexander Marble.

All interested physicians are cordially invited to attend

MASSACHUSETTS SOCIETY  
OF EXAMINING PHYSICIANS

The Massachusetts Society of Examining Physicians will have its fall meeting and dinner on Wednesday evening, December 3, at 6:30 p.m., at the Copley Plaza, Boston.

Dr. J. Grafton Love, of the Neuro Surgical Department,

Mayo Clinic, Rochester, Minnesota, will present a paper entitled, "Protruded Intervertebral Disks: A common cause of disabling backache and sciatic pain," which will be illustrated with lantern slides and motion pictures. Dr. W. Jason Mixer, chief of the Department of Neuro-Surgery, Massachusetts General Hospital, and Dr. Gilbert E. Haggart, chief of the Section of Orthopedic Surgery, Lahey Clinic, will discuss the paper.

NEW ENGLAND HEART  
ASSOCIATION

The next meeting of the New England Heart Association will be held on Monday, November 24, at 8:15 p.m. at the Massachusetts General Hospital.

## PROGRAM

Pulmonary Embolism and the Electrocardiogram Drs. Donald Murnaghan, Sylvester McGinn and Paul D. White.

Follow-Up Study of Cases of Chronic Constrictive Pericarditis Drs. Marlow B. Harrison and Paul D. White.

Phonocardiography Dr. Howard B. Sprague and Mr. Maurice B. Rappaport.

Follow-Up Study of Uncomplicated Systolic Murmurs at the Cardiac Apex or Aortic Valve Area Drs. Lyle Baker, Howard B. Sprague and Paul D. White.

Clinicopathological Study of Marked Coronary Disease Drs. Reno R. Porter and Edward F. Bland.

Interested physicians and medical students are cordially invited to attend.

NEW ENGLAND SOCIETY  
OF PHYSICAL MEDICINE

A meeting of the New England Society of Physical Medicine will be held on Wednesday, November 19, at 8 p.m., at the Danvers State Hospital, Hathorne, Massachusetts.

## PROGRAM

Introductory Remarks Dr. Clarence Alden Bonner, superintendent, Danvers State Hospital.

Neuropsychiatric Clinic, with a Discussion of Indications for Physical Medicine. Presentation of cases of multiple sclerosis, Raynaud's disease, parkinsonism, manic-depressive psychosis and schizophrenia. Dr. Leo Maletz, clinical director, Danvers State Hospital.

All members of the medical profession are cordially invited to attend.

AWARD BY THE AMERICAN  
UROLOGICAL ASSOCIATION

The American Urological Association offers an annual award, not to exceed \$500, for an essay (or essays) on the result of some specific chemical or laboratory research in urology. The amount of the award is based on the merits of the work presented, and if the Committee on Scientific Research considers none of the offerings worthy, no award will be made. Only residents in urology in recognized hospitals and physicians who have practiced urology for not more than five years may compete.

Essays should be in the hands of the secretary, Dr. Clyde L. Deming, 789 Howard Avenue, New Haven, Connecticut on or before April 1, 1942.

## UNITED STATES CIVIL SERVICE EXAMINATIONS

Health-Education Consultants, \$2600 to \$3800 a Year

To assist state, county and local health officers in dealing with problems incident to the rapid growth in industrial and governmental production and the consequent unusual concentration of population and increasing health problems, the United States Public Health Service is planning to appoint health-education consultants to various defense areas. The positions, paying \$2600 to \$3800 a year, will be filled through open competitive examinations, and the United States Civil Service Commission has just issued the examination announcement. A written test will not be given, but applicants will be rated on their qualifications as shown in their applications and corroborative evidence.

Appointees will work with local health officers and their staffs, advising them regarding methods of health education, such as individual instruction through interview, group instruction through discussions, talks, lectures and other educational technics. To qualify for the positions, applicants must have completed a four-year college course, including or supplemented by special study—or for the assistant grade, experience—in public health. In addition, they must have had experience in public-health education work co-ordinating the activities of all organized health groups in a community for the purpose of promoting a public-health program. This experience must have been in a federal, state or official local public-health department or in a voluntary agency, such as the American Red Cross or the National Tuberculosis Association.

Applications must be filed with the Civil Service Commission in Washington, D. C., not later than December 11, 1941. The examination announcement giving detailed requirements can be consulted or obtained at any first-class or second-class post office or at the central office in Washington.

## EXAMINATIONS FOR APPOINTMENTS IN THE MEDICAL CORPS OF THE UNITED STATES NAVY

Examinations for appointment as assistant surgeon (lieutenant, junior grade), United States Navy Medical Corps, will be held at all the large naval hospitals and the Naval Medical Center, Washington, D. C., on January 5 to 9, 1942, inclusive.

Applicants for appointment as assistant surgeon must be citizens of the United States, more than twenty-one but less than thirty-two years of age at the time of acceptance of appointment, and graduates of Class A medical schools who have completed at least one year of intern training in a hospital approved by the Council on Medical Education and Hospitals of the American Medical Association.

Examinations for appointment as acting assistant surgeon for intern training in naval hospitals accredited for intern training by the Council on Medical Education and Hospitals of the American Medical Association will also be held on January 5 to 9, 1942, inclusive. Applicants for appointment as acting assistant surgeon for intern training must be citizens of the United States, more than twenty-one but less than thirty-two years of age, and members of the junior or senior classes in Class A medical schools. After twelve months of intern training, acting assistant surgeons may apply for appointment as assistant surgeons in the United States Navy.

A circular of information regarding these examinations, physical requirements, rates of pay and promotion and retirement data may be obtained from the Bureau of Medicine and Surgery, Navy Department, Washington, D. C., on request. Applications for authorization to take the examination must be received at the Bureau of Medicine and Surgery three weeks before the examination.

Medical officers of the United States Navy are encouraged to develop a specialty, and are assigned, if their interest in the specialty warrants such action, to postgraduate instruction in the large naval hospitals, the Naval Medical Center, Washington, D. C., and civilian medical centers. Some of the specialties in which medical officers may seek qualifications are: surgery, medicine, ophthalmology, otolaryngology, roentgenology, laboratory, pathology, public health, psychiatry, deep-sea diving, aviation medicine (flight surgery), gas warfare, tropical medicine, medical research and so forth.

## SOCIETY MEETINGS AND CONFERENCES

### CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING SUNDAY, NOVEMBER 16

#### MONDAY, NOVEMBER 17

12 15-1:15 p.m. Clinicopathological conference. Peter Bent Brigham Hospital amphitheater.

#### TUESDAY, NOVEMBER 18

\*9 00-10 00 a.m. Medical clinic. Dr. S. J. Thannhauser. Joseph H Pratt Diagnostic Hospital.

12.00 m. Treatment of Epilepsy. Dr. H. Houston Merritt. South End Medical Club. Headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston.

12 15-1:15 p.m. Clinicoroentgenological conference. Peter Bent Brigham Hospital amphitheater.

#### WEDNESDAY, NOVEMBER 19

\*9 00-10 00 a.m. Refractory Blood Diseases. Dr. C. W. Heath. Joseph H. Pratt Diagnostic Hospital.

\*12 00 m. Clinicopathological conference. Children's Hospital

4 30 p.m. New England Oto-Laryngological Society. Massachusetts Eye and Ear Infirmary, 243 Charles Street, Boston.

8 00 p.m. Boston Society of Biologists. Harvard Biological Laboratories, Divinity Avenue, Cambridge.

\*8 15 p.m. Giovanni Battista Morgagni. Dr. Arturo Castiglioni. Boston Medical History Club. Boston Medical Library, 8 Fenway

#### FRIDAY, NOVEMBER 21

\*9 00-10 00 a.m. Anemia and Hiatus Hernia. Dr. William P. Murphy. Joseph H. Pratt Diagnostic Hospital.

\*8 15 p.m. Bone Changes and Certain Medical Diseases. Dr. Alvah H. Gordon. Evans Auditorium, Massachusetts Memorial Hospitals

#### SATURDAY, NOVEMBER 22

\*9.00-10.00 a.m. Blood Clinic. Dr. H. G. Brugsch. Joseph H Pratt Diagnostic Hospital.

\*Open to the medical profession.

## THE CONSERVATIVE TREATMENT OF OCCLUSIVE ARTERIAL DISEASE\*

IRVING S. WRIGHT, M.D.†

NEW YORK CITY

DURING the last ten years, great advances have been made in the conservative treatment of occlusive arterial disease. Major amputation in the course of the routine care of thromboangiitis obliterans has, as a result of conscientious efforts on the part of many workers throughout the country, become a rather rare occurrence. In 100 consecutive cases treated by the Vascular Clinic of the New York Post-Graduate Medical School and Hospital, major amputations were performed in only 3 cases, and figures similar to these have emanated from several sources. This is in contrast to major amputations in 50 to 70 per cent of cases prior to the use of the newer methods. We have been engaged in attempting to determine how much could be accomplished in the way of saving extremities by intensive conservative therapy. It is probable that some of these patients might have been somewhat better off financially and that their periods of disability might have been shortened by amputation earlier in the course of treatment. It is my belief, however, after studying these cases, that this figure would probably not be higher than 10 per cent. Moreover, amputation is considered the easiest course; it requires no courage, and very little can be learned from it. Conclusions that have resulted from conscientious, painstaking care of the difficult cases have often been applied with great success in the care of the less advanced lesions.

The problems associated with arteriosclerosis obliterans are more difficult. As has been pointed out previously,<sup>1</sup> this is one of the greatest economic, social and medical questions confronting the American people. There are roughly 25,000,000 people over the age of fifty in the United States today. This number is rapidly increasing, owing

to the age shift in the population. Of these persons, 60 per cent, or 15,000,000, will die of cardiovascular disease, for the most part associated with arteriosclerosis obliterans affecting the vessels of the heart, brain, kidney and other parts of the body. By contrast, only 9 per cent will die of cancer. Yet the endowments for cancer and the facilities for research in that very dramatic field have been far in excess of those available for the study of the heart and blood vessels. In spite of this neglect, material that has inconspicuously been accumulated has resulted in a better understanding of the physiologic pathology involved and has laid a sound groundwork for a more intelligent approach to the problem of treatment. The marked diminution in the amputation rate and the greater percentage of restoration in walking ability in cases of intermittent claudication have been somewhat in excess of anticipation. To date, however, this has not resulted in such satisfactory results as those obtained in the treatment of thromboangiitis obliterans.

Although there are more than fifty recognized vascular diseases and syndromes, each disease and, in fact, each patient should be studied on the basis of the exact status of the circulation of the patient. Certain forms of therapy are especially helpful in the treatment of the major occlusive arterial diseases, thromboangiitis obliterans and arteriosclerosis obliterans. I propose to discuss the conservative aspect of these forms of treatment very briefly.

### Rest

One of the most important factors in the treatment of any patient with ulceration or gangrene is rest. This should be used intelligently and on the basis of sound physiology. If the extremity is elevated, it easily becomes ischemic, and a tendency toward gangrene results. If it is kept dependent, the blood flow toward the heart be-

\*Presented at the annual meeting of the Massachusetts Medical Society, Boston, May 21, 1941.

†Director of the Department of Medicine, and professor of clinical medicine, New York Post-Graduate Medical School and Hospital, Columbia University.

comes more difficult, and congestion, with a relative ischemia, may arise. Reid<sup>2</sup> has shown that the correct level is the point at which the tip of the extremity is from 7 to 15 cm. (3 to 6 inches), below the level of the heart. At this level, gravity assists the flow of arterial blood into the limb, and the blood is not retarded in its return by too greatly increased venous back pressure. Rest should be continued until the lesion is healed, except in the specific vascular exercises enumerated below.

### *Active Vascular Exercises*

Buerger<sup>3</sup> has described vascular exercises that, since they are in wide use today, do not necessitate an elaborate description of the original suggestions. I should like to propose, however, the following modification, which applies to these exercises and is on a more sound physiologic basis than that generally applied. The physician should first elevate the patient's extremity until pallor develops. The length of time necessary for this to occur should be noted. He should then lower the extremity until rubor develops and, again, should measure the time necessary for this change. These times should be given to the patient as indicating the exact periods for elevation and dependency, rather than arbitrary units of time. From time to time in the course of treatment, these reactions should be rechecked, and the indicated changes in instructions to the patient should be given.

Allen<sup>4</sup> has suggested a modification of Buerger's exercises in which the foot is extended downward and raised by flexion of the ankle joint; the toes are turned inward and then outward, and are then separated and closed. This is helpful, if it is not too painful.

### *Care of the Extremities*

Meticulous care of the skin and nails of extremities that are suffering from impaired circulation is of vital necessity. Hands or feet that have not yet developed ulceration or gangrene should be bathed daily, and the skin and nails kept soft by the subsequent application of lanolin, olive oil or other substances having a similar effect. Nails and calluses must be pared with great care, since a very large percentage of ulcers are precipitated as a result of minute injuries that would normally heal promptly. The use of strong dekeratinizers, such as salicylic acid (in high percentage), is not to be recommended; if they are used for stubborn calluses, the situation must be kept under careful observation.

Frequent examinations should be made for evidence of epidermophytosis, since the cracks produced by this condition are frequent portals of entry for very serious secondary bacterial invaders. In my experience, soaks for potassium permanganate in dilutions of 1:7000 to 1:10,000 for thirty minutes every two or three days are usually a satisfactory method of controlling this fungus. It is advisable, however, to continue these soaks at weekly intervals long after the fungus has apparently disappeared. Gentian violet in a 5 per cent aqueous solution may be used, but the stronger antiseptics and fungicides are distinctly contraindicated, since the condition of the tissues is frequently such that more harm than good results.

When ulceration occurs, the problem immediately becomes more serious and emergent. This fact is too often not recognized or acted on by the physician. There is a dictum in our clinic: It is far better surgery to take meticulous care of a minute lesion than it is to perform a major amputation in the amphitheater. The cutting away of the involved area before the available circulation has been adequately improved usually results in a larger ulceration, with an unfavorable result. Efforts, such as those subsequently outlined in this paper, should be made to improve the blood supply, since that is the primary problem. Soaks should be used. All strong antiseptics, such as iodine and the mercurials, should be avoided: they frequently do more harm to the delicate new endothelial buds and new cells than to the infecting organisms. Gradually, by careful daily dissection, sloughs and other debris should be removed, thus allowing the endothelial, epithelial and connective-tissue cells to extend in from the edges. It is essential to make certain that purulent material is not accumulating under the scabs, which often appear healthy and innocuous. Lifting of the edges frequently reveals pus that is eroding and undermining the tissues covered by and surrounding the scab. It is imperative to maintain adequate drainage by removing or cutting windows in the scab; this should be followed immediately by a saline soak.

If the situation results in gangrene of digits or of an entire hand or foot, careful observation should be routine for evidence of rapid extension of infection, such as lymphangitis or a septic syndrome. When this occurs, amputation may be necessary. When, however, the gangrene is slowly extending, time should be allowed for self-amputation whenever possible, since the circulation is usually then adequate for healing at the point of separation. One can help this along by keeping the point of separation clean and by cutting per-

sisting tendons and other fibrous tissue a little at a time. Finally, the digit may be lifted off with little or no discomfort and without a local anesthetic, which is apt to be harmful because of the pressure produced in the tissues. Adrenalin in an anesthetic is especially contraindicated, since it produces vasoconstriction; I have seen cases in which massive gangrene was precipitated by this substance. If the tip of a phalanx protrudes beyond the level of the separation, it will probably be necessary to remove it down to that level on the shaft of the bone. This may be accomplished slowly, in small fragments, by the use of a scalpel—after which healing will tend to take place more satisfactorily. After each dressing, a thirty-minute soak in sterile physiologic saline solution at a temperature of 96°F. helps to ensure drainage and cleanliness, following which the area is dried sterily and kept under dry thermostatically controlled heat, as described elsewhere.

Nerve sections are occasionally used on our service if we are unable to control the pain in any other way, but judging by the results in other clinics as well as those in our own, we are inclined to believe that too frequently the claims of complete relief represent wishful thinking on the part of the surgeon and a disregard of the pain and especially the paresthesias of which the patients complain when permitted to voice their woes. Similar complaints of very annoying paresthesias frequently follow the use of alcohol block of the lumbosacral sympathetic nerves, and surgeons who have never noted such results should spend more time listening to their patients. Nevertheless, one is sometimes obliged to use these measures in an endeavor to bring all possible collateral circulation into play before the gangrene becomes widespread.

A discussion of the surgical technics that are indicated when conservative therapy fails and that require the finest judgment is not within the scope of this paper. It is most important that, when amputation is to be performed, the correct level be determined on the basis of adequate circulation for healing by careful clinical study. In doubtful cases, tests such as oscillometric readings, arteriograms, histaminase-flare reactions, and vasodilatation tests prove useful.

#### *Abstinence from Tobacco*

It hardly seems necessary to elaborate on the need for total and permanent abstinence from tobacco in the care of occlusive arterial disease, since great volumes of experimental evidence confirm the studies of Maddock and Coller,<sup>2</sup> Barker,<sup>6</sup> Wright and Moffat<sup>7</sup> and Lampson.<sup>8</sup> Thrombo-

angiitis obliterans appears to be more specifically aggravated by smoking than arteriosclerosis obliterans,<sup>9-11</sup> but in the latter disease it is essential to realize that, whereas the major vessels may be occluded, the small collateral branches (on which the life of the tissues depends) are subject to spasm. If the blood supply has been reduced by disease to the bare minimum necessary for the life of the tissues, it is disastrous to produce repeated spasm in these small vessels and thus reduce the blood supply to a point incompatible with the life of the tissues. For further investigation on this subject, one may find a review of the points involved in a recent symposium<sup>11</sup> on vascular disease. Clinical experience has shown that if a physician wishes to obtain good results in the treatment of either of these conditions he must impress his patient with the fact that his outlook depends on conformity to the edict, "No smoking, now and forever."

#### *Alcohol*

As a more cheerful and compensatory form of treatment, the use of alcohol may be prescribed. Alcohol has been demonstrated to be a marked vasodilator, and it is also of considerable value as a sedative. We therefore recommend the liberal use of alcohol almost to the point of inebriation during the acute, painful periods of ulceration or gangrene, and its moderate daily use after the lesions have healed and the patient has again become active. It is our experience that patients rarely object to this form of therapy.

#### *Baths*

Various types of baths have been used. We formerly used contrast baths, but there are several reasons why these have been largely abandoned in our clinic. In the first place, the best containers reach only to the knees, and too often the area of blockage is well above that level, so that the changes in the metabolic demands caused by the baths cannot be adequately compensated for by the vessels. Secondly, when already damaged vessels are forced into sudden vasospasm, they may remain closed, thus complicating the picture. Thirdly, many patients complain of the severe pain that occurs during the cold phase. In place of these, we use a modification of the sitz bath, in which the patient sits in a tub containing at least 30 cm. (12 inches) of water at a temperature of 34 to 38°C. (95 to 100°F.) for thirty minutes once a day. This tends to produce vasodilatation of the patient's vessels from the hips down, and is a very satisfactory form of therapy except that it is not recommended when open lesions are present.

## Soaks

In the place of wet dressings, which have largely been abandoned, because unless watched with rare acuity they become cold and chill the small endothelial buds into inactivity, we have used soaks, two or three times daily, for fifteen to thirty minutes. We use a boric acid solution or a physiologic solution of sodium chloride at 36 to 38°C. (96 to 100°F.). Great care should be taken to keep the temperature within these limits. After each soak, the foot is carefully dried and placed under a thermostatically controlled cradle, thus preventing chilling and at the same time allowing for softening of the crusts and adequate drainage.

## Heat

It is probable that the use of local heat has done far more harm than good in the treatment of peripheral vascular disease. I have seen more than 50 cases in which severe ulceration, massive necrosis or gangrene was primarily produced by the extensive use of diathermy or short-wave, infrared or other forms of local heat applied to an area where there was a marked arterial impairment resulting from peripheral vascular disease. When intensive heat is used locally in the presence of marked impairment of the circulation, greatly increased metabolic demands cannot be met, since insufficient blood is available. Furthermore, intensive heat cannot be carried away, so that the tissue rapidly becomes broiled, almost as if it were a piece of meat. I have seen cases in which holes produced by burning, with subsequent necrosis, extended through the flesh of the patients' feet until finally the bones of the feet were exposed. Seven of these patients have lost their legs, and 2 have died. It is therefore vital to use only controlled heat, with the temperature between 31 and 36°C. (88 and 96°F.), depending on the needs of the patient. This can best be accomplished by means of a thermostatically controlled light.
